The content, statements, views, and opinions herein are the sole expression of the respective authors and not that of Jones & Bartlett Learning, LLC. Reference herein to any specific commercial product, process, or service by trade name, trademark, manufacturer, or otherwise does not constitute or imply its endorsement or recommendation by Jones & Bartlett Learning, LLC, and such reference shall not be used for advertising or product endorsement purposes. All trademarks displayed are the trademarks of the parties noted herein. *Advanced Emergency Care and Transportation of the Sick and Injured, Fourth Edition* is an independent publication and has not been authorized, sponsored, or otherwise approved by the owners of the trademarks or service marks referenced in this product.

There may be images in this book that feature models; these models do not necessarily endorse, represent, or participate in the activities represented in the images. Any screenshots in this product are for educational and instructive purposes only. Any individuals and scenarios featured in the case studies throughout this product may be real or fictitious but are used for instructional purposes only.

The procedures and protocols in this book are based on the most current recommendations of responsible medical sources available at the time of publication. The American Academy of Orthopaedic Surgeons and the publisher, however, make no guarantee as to, and assume no responsibility for, the correctness, sufficiency, or completeness of such information or recommendations. Other or additional safety measures may be required under particular circumstances. Clinicians should use their own, independent medical judgment, in addition to open discussion with the patient, when developing patient care recommendations and treatment plans.

This textbook is intended solely as a guide to the appropriate procedures to be employed when rendering emergency care to the sick and injured. It is not intended as a statement of the standards of care required in any particular situation, because circumstances and the patient's physical condition can vary widely from one emergency to another. Nor is it intended that this textbook shall in any way advise emergency personnel concerning legal authority to perform the activities or procedures discussed. Such local determination should be made only with the aid of legal counsel. The patients described in the *You are the Provider* and *Assessment in Action* scenarios throughout the text are fictitious.

Contents

Section 1 Preparatory

1

1 EMS Systems

2

Introduction	3
Course Description	3
AEMT Training: Focus and Requirements	5
Licensure Requirements	6
Overview of the EMS System	7
History of EMS	7
Levels of Training	8
Public Basic Life Support and Immediate Aid	11
Emergency Medical Responder	12
Emergency Medical Technician	12
Advanced Emergency Medical Technician	13
Paramedic	13
Components of the EMS System	13
Public Access	14
Communication Systems	14
Clinical Care	15
Human Resources	15
Medical Direction and Control	16
Legislation and Regulation	16
Integration of Health Services	17
Mobile Integrated Healthcare and Community Paramedicine	18
Evaluating Quality and Safety	18
Information Systems	19
System Finance	20
Education Systems	20
Prevention and Public Education	21
EMS Research	23
Transport Considerations and Communication	24
Transport to Specialty Centers	24
Interfacility Transports	25
Working With Hospital Staff	25
Working With Public Safety Agencies	25
Roles and Responsibilities of AEMTs	25
Professional Attributes	26

2 Workforce Safety and Wellness

33

Introduction	34
Protection From Infectious Diseases	34
Routes of Transmission	35
Risk Reduction and Prevention	37
Standard Precautions	37
Proper Hand Hygiene	39
Gloves	39
Eye Protection	42
Gowns	42

Masks, Respirators, and Barrier Devices	42
Proper Disposal of Sharps	43
Employer Responsibilities	44
Establishing an Infection Control Routine	44
Immunity	47
Immunizations	48
General Postexposure Management	49
Postexposure Prophylaxis and Treatment for Significant Exposure	50
Illness and Injury Prevention	51
Scene Safety and Personal Protection	52
Scene Hazards	53
Protective Clothing: Preventing Injury	58
Cold Weather Clothing	59
Turnout Gear	59
Gloves	60
Helmets	60
Boots	61
Eye Protection	61
Ear Protection	61
Skin Protection	61
Body Armor	62
Stress	62
Stress Management	64
Burnout	66
Compassion Fatigue	66
Peer Support and Suicide Prevention	67
Wellness	68
Nutrition	69
Exercise and Relaxation	70
Avoidance of Tobacco Use or Cessation	71
Sleep	71
Disease Prevention	72
Balancing Work, Family, and Health	72
Substance Abuse	73
Workplace Issues	74
Diversity on the Job	74
Sexual Harassment	74
Death and Dying	75
The Grieving Process	76
Working With Family Members	76
Working With the Patient	77
Dealing With the Death of a Child	79
Caring for Critically Ill and Injured Patients	80
Avoid Sad and Grim Comments	80
Orient the Patient	80
Be Honest	80
Initial Refusal of Care	81
Allow for Hope	81
Locate and Notify Family Members	81
Injured and Critically Ill Children	81
Uncertain Situations	82

3 Medical, Legal, and Ethical Issues 89

Introduction	90
Scope of Practice	90
Standards of Care	91
Standards Imposed by Local Custom	92
Standards Imposed by Law	92
Professional or Institutional Standards	93
Standards Imposed by Textbooks	94
EMS-Enabling Legislation	94
Standards Imposed by States	94
Negligence	95
Duty	96
Breach of Duty	96
Damages	97
Proximate Cause	97
Abandonment	97
Assault, Battery, Kidnapping, and False Imprisonment	98
Defamation, Libel, and Slander	99
Good Samaritan Laws and Immunity	99
Consent	100
Expressed Consent	101
Implied Consent	102
Minors and Consent	103
Involuntary Consent	104
Forcible Restraint	104
The Right to Refuse Treatment	105
Advance Directives	106
Physician Orders for Life-Sustaining Treatment	108
Ethical Principles and Moral Obligations	108
Confidentiality	109
Health Insurance Portability and Accountability Act	110
Social Media	111
Records and Reports	111
Mandatory Reporting Requirements	112
Scene of a Crime	112
The Deceased	113
Physical Signs of Death	113
Presumptive Signs of Death	113
Definitive Signs of Death	114
Coroner and Medical Examiner Cases	114
Special Situations	115
Organ Donors	115
Medical Identification Insignia	115

4 Communications and Documentation 123

Introduction	124
Therapeutic Communication	125
Age, Culture, and Personal Experience	126
Nonverbal Communication	127
Verbal Communication	129
Communicating With Specific Types of Patients	134
Transfer of Patient Care	139
Communications Systems and Equipment	141
Regulation of Radio and Telephone Communications	142
Radio Communications	142
Cell/Satellite Telephones	146
Digital Equipment	146
Other Communications Equipment	147
The EMS Communication Process	149
Notification	149

Dispatch	150
En Route Communications	151
Communicating With Medical Control and Hospitals	151
Effective Radio Communications	155
Written Communications and Documentation	156
Types of PCRs	157
Legal Issues of a PCR	158
Components of a PCR	160
Medical Terminology	162
Reporting Errors	164
Minimum Requirements and Billing	165
Documenting Refusal of Care	166
Special Reporting Situations	167
Submitting the Report	170

5 Medical Terminology 179

Introduction	180
Origins	180
Eponyms	180
Homonyms	182
Antonyms	182
Synonyms	182
Components of a Medical Term	183
Prefixes	183
Numerical Prefixes	184
Suffixes	184
Word Roots	184
Colors	185
Combining Forms and Vowels	185
Compound Words	186
Plural Endings	187
Topographic Anatomy	187
Anatomic Planes and Axes of the Body	187
Specific Areas of the Body	189
Body Cavities	190
Directional Terms	191
Movement and Positional Terms	193
Other Directional Terms	194
Prefixes Indicating Position, Direction, and Location	195
Position of the Patient	195
Abbreviations, Acronyms, and Symbols	197
Medical Abbreviations	198
Error-Prone Abbreviations	198
Symbols	198
Medical Terminology Related to Pharmacology	198
Master Tables	199

6 Lifting and Moving Patients 215

Introduction	216
Body Mechanics	217
Anatomy Review	217
Proper Lifting Technique	219
Proper Hold	219
Directions and Commands	221
Principles of Safe Reaching and Pulling	222
Moving a Patient Across a Bed	223
The Two-Person Body Drag	223
Log Rolling a Patient	224
Rolling a Wheeled Ambulance Stretcher	224
Lifting and Carrying a Patient on a Backboard or Stretcher	225
Weight and Distribution	225

Planning the Move	226
The Diamond Carry	226
The One-Handed Carrying Technique	228
Emergency Moves	228
Urgent Moves	230
Rapid Extrication Technique	231
Nonurgent Moves	235
Direct Ground Lift	236
Extremity Lift	237
Transfer Moves	237
Geriatrics	241
Bariatrics	243
Patient-Moving Equipment	243
The Wheeled Ambulance Stretcher	243
Bariatric Stretchers	245
Pneumatic and Electronic Powered Wheeled Stretchers	245
Loading the Wheeled Stretcher Into an Ambulance	246
Portable/Folding Stretchers	248
Flexible Stretchers	248
Backboards	248
Vacuum Mattresses	249
Basket Stretchers	250
Scoop Stretchers	250
Stair Chairs	250
Moving a Patient on Stairs With a Backboard	252
Neonatal Isolettes	253
Decontamination	253
Patient Positioning	253
Medical Restraints	254
Personnel Considerations	254

SECTION 2 The Human Body and Human Systems

261

7 The Human Body

262

Introduction	263
Cells	263
Cell Structure	263
Cell Membrane	263
Cytoplasm	264
Organelles	264
Nucleus	266
Life Cycle of the Cell	267
Interphase	267
Cell Division and Cytoplasmic Division	267
Differentiation	267
Cell Division and Cancer	267
Cellular Respiration	268
Glycolysis	268
Krebs Cycle	269
Electron Transport Chain	269
Cellular Transport Mechanisms	270
Diffusion	270
Filtration	270
Facilitated Diffusion	271
Osmosis	272
Body Fluid Balance	272
Organ Systems	274
The Skeletal System: Anatomy	274
Bones	274

Joints	276
The Axial Skeleton	278
The Neck	281
The Spinal Column	282
The Thorax	283
The Appendicular Skeleton	284
The Skeletal System: Physiology	289
The Musculoskeletal System	290
Skeletal Component	290
Muscular Component	291
The Respiratory System: Anatomy	293
The Upper Airway	293
The Lower Airway	295
Muscles of Breathing	297
The Respiratory System: Physiology	299
Respiration	299
Lung Volumes	304
Characteristics of Normal Breathing	305
The Circulatory System: Anatomy	305
The Heart	306
The Vascular System	312
Blood Composition	320
The Circulatory System: Physiology	322
Normal Circulation in Adults	323
Inadequate Circulation in Adults	323
The Function of Blood	324
The Lymphatic System	325
Lymphatic Vessels	325
The Nervous System: Anatomy and Physiology	326
The Central Nervous System	326
The Diencephalon	330
The Peripheral Nervous System	330
The Eye	332
The Integumentary System (Skin): Anatomy	333
The Integumentary System (Skin): Physiology	335
The Digestive System: Anatomy	336
The Abdomen	336
Mouth	337
Oropharynx	338
Esophagus	338
Stomach	338
Pancreas	338
Liver	338
Small Intestine	339
Large Intestine	339
Appendix	339
Rectum	339
The Digestive System: Physiology	339
The Endocrine System: Anatomy and Physiology	340
The Pituitary Gland and the Hypothalamus	341
The Thyroid Gland	341
The Parathyroid Glands	341
The Pancreas	341
The Adrenal Glands	342
The Reproductive Glands and Hormones	343
The Urinary System: Anatomy and Physiology	343
The Genital System: Anatomy and Physiology	344
The Male Reproductive System and Organs	344
The Female Reproductive System and Organs	345
Life Support Chain	347

8 Pathophysiology

367

Introduction	368
Adaptations in Cells and Tissues	368

Disturbances in Fluid Balance	369
Edema	370
Isotonic Fluid Deficit	371
Electrolyte Imbalances	371
Sodium	371
Potassium	371
Calcium	372
Phosphate	373
Magnesium	373
Disturbances of Acid-Base Balance	374
Types of Acid-Base Imbalance	374
Cellular Injury	378
Hypoxic Injury	379
Chemical Injury	379
Infectious Injury	379
Immunologic and Inflammatory Injury	381
Injurious Genetic Factors	382
Injurious Nutritional Imbalances	382
Injurious Physical Agents or Conditions	382
Apoptosis	382
Abnormal Cell Death	382
Hypoperfusion	383
Types of Shock	384
Central Shock	384
Peripheral Shock	386
Management of Shock	386
Multiple Organ Dysfunction Syndrome	387
The Body's Self-Defense Mechanisms	389
Anatomic Barriers	389
Immune Response	389
Inflammatory Response	396
Chronic Inflammatory Responses	400
Variances in Immunity and Inflammation	400
Hypersensitivity	400
Immune Deficiencies	404
Factors That Cause Disease	405
Controllable Versus Uncontrollable Risk Factors	405
Analysis of Disease Risk	406
Common Familial Diseases and Associated Risk Factors	406
Stress and Disease	415
General Adaptation Syndrome	416
Effects of Chronic Stress	418

9 Life Span Development 429

Introduction	430
Neonates (Birth to 1 Month) and Infants (1 Month to 1 Year)	430
Physical Changes	430
Psychosocial Changes	433
Toddlers (1 to 3 Years) and Preschoolers (3 to 6 Years)	434
Physical Changes	434
Psychosocial Changes	436
School-Age Children (6 to 12 Years)	437
Physical Changes	437
Psychosocial Changes	437
Adolescents (12 to 18 Years)	437
Physical Changes	437
Psychosocial Changes	438
Early Adults (19 to 40 Years)	439
Physical Changes	439
Psychosocial Changes	439
Middle Adults (41 to 60 Years)	440

Physical Changes	440
Psychosocial Changes	440
Older Adults (61 Years and Older)	440
Physical Changes	440
Psychosocial Changes	445

SECTION 3 Patient Assessment 451

10 Patient Assessment 452

Introduction	455
Clinical Decision Making and Critical Thinking	457
Scene Size-up	460
Ensure Scene Safety	461
Determine Mechanism of Injury/Nature of Illness	462
Take Standard Precautions	464
Determine the Number of Patients	465
Consider Additional or Specialized Resources	466
Primary Survey	468
Form a General Impression	469
Assess Level of Consciousness	470
Assess the Airway	472
Assess Breathing	474
Assess Circulation	476
Assess the Patient for Disability	481
Expose Then Cover	481
Performing a Rapid Full-Body Scan	482
Identify and Treat Life Threats	485
Determine Priority of Patient Care and Transport	485
History Taking	489
Investigate the Chief Complaint	489
Investigate the History of Present Illness (OPQRST)	491
Investigate the Past Medical History (SAMPLE History)	494
Secondary Assessment	502
Assess Vital Signs Using the Appropriate Monitoring Devices	503
Systematically Assess the Patient: Full-Body Exam	506
Systematically Assess the Patient: Focused Assessment	506
Reassessment	530
Repeat the Primary Survey	530
Reassess Vital Signs	531
Reassess the Chief Complaint	531
Recheck Interventions	531
Identify and Treat Changes in the Patient's Condition	531
Reassess the Patient	531

SECTION 4 Airway 539

11 Airway Management 540

Introduction	542
Anatomy Review	542
The Upper Airway	543
The Lower Airway	545
Physiology of Breathing	546
Ventilation	548

Oxygenation	551
Respiration	551
Neural Control	553
Chemical Stimuli	553
Pathophysiology of Respiration	554
Hypoxia	554
Ventilation-Perfusion Ratio and Mismatch	554
Factors Affecting Ventilation	555
Factors Affecting Oxygenation and Respiration	556
Acid-Base Balance	558
Patient Assessment: Airway Evaluation	559
Recognizing Adequate Breathing	559
Recognizing Inadequate Breathing	559
Assessment of Respiration	563
Opening the Airway	568
Head Tilt–Chin Lift Maneuver	569
Jaw-Thrust Maneuver	570
Tongue-Jaw Lift Maneuver	571
Maintaining the Airway	572
Suctioning	572
Suctioning Equipment	572
Techniques of Suctioning	574
Tracheobronchial Suctioning of an Intubated Patient	574
Basic Airway Adjuncts	576
Oropharyngeal Airway	576
Nasopharyngeal Airway	578
Supplemental Oxygen	580
Supplemental Oxygen Equipment	580
Operating Procedures	583
Hazards of Supplemental Oxygen	585
Oxygen-Delivery Devices	586
Nonrebreathing Mask	586
Nasal Cannulas	587
Partial Rebreathing Mask	587
Venturi Mask	587
Tracheostomy Masks	588
Oxygen Humidifiers	588
Assisted and Artificial Ventilation	589
Artificial Ventilation	589
Mouth-to-Mouth and Mouth-to-Mask Ventilation	591
The Bag-Mask Device	592
MTV Devices	597
Automatic Transport Ventilators/Resuscitators	597
Continuous Positive Airway Pressure	598
Indications for CPAP	599
Contraindications to CPAP	599
Application of CPAP	600
Complications of CPAP	600
Special Considerations	602
Gastric Distention	602
Laryngectomy, Tracheostomy, Stoma, and Tracheostomy Tubes	602
Suctioning of a Stoma	603
Ventilation of Stoma Patients	604
Tracheostomy Tubes	604
Dental Appliances	604
Facial Bleeding	606
Foreign Body Airway Obstruction	607
Recognition	607
Supraglottic Airway Devices	608
King LT Airway	608
The Laryngeal Mask Airway	610

i-gel	615
The Cobra Perilaryngeal Airway	615
Multilumen Airway Devices	618
Combitube	618
Assisting With ALS Airway Procedures	620
Assisting With Placement of Advanced Airways	620

SECTION 5 Pharmacology

635

12 Principles of Pharmacology

636

Introduction	637
Drug Terminology	638
Medication Names	639
Sources of Drug Information	639
US Regulation of Pharmaceuticals	640
Drug-Related Legislation	640
Manufacturing-Related Regulations	642
Government Agencies That Regulate Drugs	642
The Drug-Approval Process	642
Animal Studies	642
Clinical Trials	642
Drug Storage and Security of Controlled Substances	643
Special Considerations in Drug Therapy	643
Pregnant Patients	643
Pediatric Patients	644
Geriatric Patients	645
Scope of Practice	645
Methods of Drug Classification	645
Nervous System Classifications	646
Analgesics and Antagonists	649
Anxiety, Sedative, and Hypnotic Drugs	650
Anticonvulsants	650
Stimulants	651
Depressants	651
Psychotherapeutic Drugs	651
Drugs Affecting the Cardiovascular System	651
Drugs Affecting the Respiratory System	653
Drugs Affecting the Pancreas	654
Drugs Affecting the Immunologic System	654
Vitamins and Minerals	654
Fluids and Electrolytes	654
Drug Forms	654
Solid Drugs	654
Liquid Drugs	655
Metered-Dose Inhalers	656
Topical Medications	656
Transcutaneous Medications	656
Gels	657
Gases	658
Routes of Drug Administration	658
Pharmacokinetics: Movement of Drugs Through the Body	659
Principles of Pharmacokinetics	659
Drug Absorption	660
Drug Distribution	660
Biotransformation	660
Drug Elimination	660
Pharmacodynamics	662
Mechanism of Action	662
Drug-Response Relationship	663

Factors Influencing Medication Interactions	664
Predictable Responses	664
Iatrogenic Responses	664
Unpredictable Responses	664
Reducing Medication Errors	665
Specific Medications	668

13 Vascular Access and Medication Administration 687

Introduction	689
Medication Administration	690
Medical Direction	690
The AEMT's Responsibility Associated With Drug Orders	690
Specific Medications	692
Basic Cell Physiology	692
Electrolytes	692
Body Fluid Composition	693
Fluid and Electrolyte Movement	694
Fluid Compartments	696
Fluid Balance	697
IV Fluid Composition	698
Types of IV Solutions	699
IV Techniques and Administration	700
Assembling Your Equipment	701
Choosing an IV Solution	701
Choosing an Administration Set	702
Choosing an IV Site	705
Choosing a Catheter	707
Inserting the IV Catheter	708
Drawing Blood	710
Securing the Line	710
Changing an IV Bag	710
Discontinuing the IV Line	711
Alternative IV Sites and Techniques	715
Troubleshooting IV Therapy	716
Possible Complications of IV Therapy	716
Pediatric IV Therapy Considerations	720
Geriatric IV Therapy Considerations	720
Intraosseous Infusion	721
IO Sites	722
Equipment for IO Infusion	723
Performing IO Infusion	725
Potential Complications of IO Infusion	728
Contraindications to IO Infusion	728
Mathematical Principles Used in Pharmacology	728
Mathematical Principles Used in Pharmacology	729
Calculating Drip Rates	732
Calculating Medication Doses	733
Pediatric Doses	735
Steps for Administering by Specific Routes	735
Administering Enteral Medications	735
Administering Parenteral Medications	736

The Role of the Nervous System	768
Regulation of Blood Flow	769
Respiration and Oxygenation	770
Pathophysiology	770
Compensation for Decreased Perfusion	772
Shock-Related Events at the Capillary and Microcirculatory Levels	774
Multiple-Organ Dysfunction Syndrome	776
Respiratory Impairment	776
Causes of Shock	777
Types of Shock	777
Hypovolemic Shock	777
Cardiogenic Shock	779
Obstructive Shock	780
Distributive Shock	780
The Progression of Shock	785
Compensated Shock	786
Decompensated Shock	786
Irreversible Shock	787
Patient Assessment	787
Scene Size-up	787
Primary Survey	788
History Taking	789
Secondary Assessment	789
Reassessment	789
Emergency Medical Care for Shock	790
IV Therapy	791
Special Considerations in Fluid Resuscitation	793
Assessment and Management of Specific Types of Shock	794
Treating Hypovolemic Shock	794
Treating Cardiogenic Shock	794
Treating Obstructive Shock	795
Treating Septic Shock	795
Treating Neurogenic Shock	796
Treating Anaphylactic Shock	796
Treating Psychogenic Shock	797

15 BLS Resuscitation 803

Introduction	805
Elements of BLS	805
The Components of CPR	807
Assessing the Need for BLS	809
Basic Principles of BLS	810
Automated External Defibrillation	810
AED Use in Children	811
Special AED Situations	811
Positioning the Patient	812
Check for Breathing and a Pulse	812
Provide External Chest Compressions	813
Proper Hand Position and Compression Technique	813
Opening the Airway and Providing Artificial Ventilation	816
Opening the Airway in Adults	816
Recovery Position	817
Breathing	818
Provide Artificial Ventilations	818
One-Rescuer Adult CPR	820
Two-Rescuer Adult CPR	821
Switching Positions	822
Crew Resource Management	822
Code Team Member Roles	823
Code Team Leader Roles	824

SECTION 6 Shock and Resuscitation 765

14 Shock 766

Introduction	767
Physiology of Perfusion	767
Cardiac Output	768

ROSC and Postresuscitation Support	824
Devices and Techniques to Assist Circulation	825
Active Compression-Decompression CPR	826
Impedance Threshold Device	826
Mechanical Piston Device	827
Load-Distributing Band CPR or Vest CPR	827
Infant and Child CPR	828
Determining Responsiveness	828
Check for Breathing and a Pulse	830
Airway	831
Provide Rescue Breathing	833
Interrupting CPR	834
When Not to Start CPR	835
When to Stop CPR	837
Foreign Body Airway Obstruction in Adults	838
Recognizing Foreign Body Airway Obstruction	838
Removing a Foreign Body Airway Obstruction in an Adult	839
Foreign Body Airway Obstruction in Infants and Children	841
Removing a Foreign Body Airway Obstruction in a Child	842
Removing a Foreign Body Airway Obstruction in Infants	842
Special Resuscitation Circumstances	844
Opioid Overdose	844
Cardiac Arrest in Pregnancy	845
Grief Support for Family Members and Loved Ones	845
Education and Training for the AEMT	846
Education and Training for the Public	847

SECTION 7 Medical

853

16 Medical Overview 854

Introduction	855
Types of Medical Emergencies	855
Patient Assessment	856
Scene Size-up	857
Primary Survey	857
History Taking	858
Secondary Assessment	859
Reassessment	859
Management: Transport and Destination	859
Scene Time	860
Type of Transport	860
Destination Selection	861
Infectious Diseases	862
General Assessment Principles	862
General Management Principles	862
Epidemic and Pandemic Considerations	863
Common or Serious Communicable Diseases	863
Human Immunodeficiency Virus Infection	863
Influenza	865
Hepatitis	865
Herpes Simplex	868
Syphilis	868
Meningitis	868
Tuberculosis	868
Pertussis	870
Methicillin-Resistant <i>Staphylococcus aureus</i>	870

New and Emerging Diseases	870
Global Health Issues	871
Middle East Respiratory Syndrome Coronavirus	871
Coronavirus Disease 2019 (COVID-19)	871
Ebola	873
Zika Virus	873
Travel Medicine	874
Conclusion	874

17 Respiratory Emergencies 881

Introduction	882
Anatomy and Physiology Review	882
Anatomy Review	882
Physiology Review	885
Pathophysiology	887
Gas Exchange Interface	887
Carbon Dioxide Retention and Hypoxic Drive	889
Hypoventilation	890
Hyperventilation	891
Causes of Dyspnea	891
Upper or Lower Airway Infection	892
Acute Pulmonary Edema	895
Chronic Obstructive Pulmonary Disease	896
Asthma	898
Anaphylactic Reactions	898
Spontaneous Pneumothorax	899
Pleural Effusion	899
Pulmonary Embolism	900
Obstruction of the Airway	901
Environmental/Industrial Exposure	901
Cystic Fibrosis	902
Age-Related Conditions	902
Patient Assessment	906
Scene Size-up	906
Primary Survey	906
History Taking	909
Secondary Assessment	912
Reassessment	915
Emergency Medical Care	915
Perform Standard Interventions	915
Decrease the Work of Breathing	915
Provide Supplemental Oxygen	916
Administer a Bronchodilator	916
Consider Fluid Balance	922
Support or Assist Ventilation	922
Assessment and Management of Specific Conditions	923
Upper or Lower Airway Diseases	923
Acute Pulmonary Edema	924
Aspiration	924
Chronic Obstructive Pulmonary Disease	924
Asthma	925
Anaphylactic Reactions	926
Spontaneous Pneumothorax	926
Pleural Effusion	927
Pulmonary Embolism	927
Hyperventilation	927
Obstruction of the Airway	927
Environmental/Industrial Exposure	927
Age-Related Assessment and Management	928
Tracheostomy Dysfunction	929
Epidemic and Pandemic Considerations	929
COVID-19	930

18 Cardiovascular Emergencies**939**

Introduction	940
Anatomy and Physiology Review	941
Anatomy Review	941
Physiology Review	945
Pathophysiology	946
Atherosclerosis	947
Acute Coronary Syndrome	948
Pulmonary Edema	956
Hypertensive Emergencies	956
Patient Assessment	957
Scene Size-up	957
Primary Survey	957
History Taking	958
Secondary Assessment	961
Reassessment	962
Emergency Medical Care for Chest Pain or Discomfort	963
Administering Nitroglycerin	964
Heart Surgeries and Cardiac Assistive Devices	965
Automatic Implantable Cardiac Defibrillators	967
External Defibrillator Vest	968
Left Ventricular Assist Devices	968
Cardiac Arrest	969
Automated External Defibrillation	969
Emergency Medical Care for Cardiac Arrest	972
Cardiopulmonary Resuscitation	972
Preparation for Defibrillation	974
Performing Defibrillation	974
Patient Care After AED Shocks	977
Cardiac Arrest During Transport	978
Management of Return of Spontaneous Circulation	978
Cardiac Monitoring	979

19 Neurologic Emergencies**991**

Introduction	992
Anatomy and Physiology Review	993
Neurons and Impulse Transmission	994
Pathophysiology	995
Stroke	997
Conditions That May Mimic Stroke	1002
Seizures	1003
Altered Mental Status	1007
Syncope	1009
Headache	1009
Patient Assessment	1009
Scene Size-up	1010
Primary Survey	1011
History Taking	1014
Secondary Assessment	1015
Reassessment	1020
Emergency Medical Care	1020
Stroke	1021
Transient Ischemic Attack	1023
Seizures	1023
Syncope	1025
Headache	1026

20 Gastrointestinal and Urologic Emergencies**1033**

Introduction	1034
Anatomy and Physiology Review	1034
The Gastrointestinal System	1034
Additional Abdominal Organs	1036

The Genital System	1036
The Urinary System	1036
Pathophysiology	1037
Causes of Acute Abdomen	1039
Gastrointestinal Hemorrhage	1040
Nonhemorrhagic Conditions	1043
Chronic Inflammatory Conditions	1044
Ulcerative Colitis	1044
Irritable Bowel Syndrome	1045
Crohn Disease	1046
Pathophysiology of the Urinary System	1046
Pathophysiology of the Renal System	1047
Kidney Stones	1047
Kidney Disease	1047
End-Stage Renal Disease	1048
Pathophysiology of Female Reproductive Organs	1048
Pathophysiology of the Male Genital Tract	1048
Epididymitis and Orchitis	1048
Priapism	1049
Benign Prostate Hypertrophy	1049
Testicular Masses	1049
Testicular Torsion	1049
Pathophysiology of Other Organ Systems	1049
Patient Assessment	1050
Scene Size-up	1050
Primary Survey	1050
History Taking	1053
Secondary Assessment	1054
Reassessment	1056
Emergency Medical Care	1056
Renal Dialysis	1057
Disequilibrium Syndrome	1059
Air Embolism	1060

21 Endocrine and Hematologic Emergencies**1067**

Introduction	1068
Anatomy and Physiology Review:	
The Endocrine System	1068
Pituitary Gland	1069
Thyroid Gland	1070
Pancreas	1070
The Role of Glucose and Insulin	1070
Pathophysiology of the Endocrine System	1071
Hypothyroidism and Hyperthyroidism	1072
Diabetes Mellitus	1072
Type 1 Diabetes Mellitus	1075
Type 2 Diabetes Mellitus	1076
Prediabetes	1077
Gestational Diabetes	1078
Hypoglycemia	1079
Hyperglycemia and Diabetic Ketoacidosis	1081
Hyperosmolar Hyperglycemic Nonketotic Syndrome	1084
Patient Assessment of Endocrine Emergencies	1085
Scene Size-up	1086
Primary Survey	1086
History Taking	1087
Secondary Assessment	1088
Reassessment	1088
Emergency Medical Care of Endocrine Emergencies	1089
General Management	1089
Management of Hypoglycemia	1089
Management of Hyperglycemia and DKA	1092
Management of HHNS	1092

Hematologic Emergencies	1093	Sedatives and Hypnotics	1159
Anatomy and Physiology Review: Hematology	1093	Cardiac Medications	1160
Blood and Plasma	1093	Other Medications	1161
Blood-Forming Organs and RBC Production	1094	Organophosphates	1163
Blood Classifications	1095	Carbon Monoxide	1164
Pathophysiology of Hematologic Emergencies	1095	Metals	1165
Sickle Cell Disease	1095	Miscellaneous Substances	1166
Anemia	1097	Food Poisoning	1169
Clotting Disorders	1098	Poisonous Plants	1169
Disseminated Intravascular Coagulation	1099		
Patient Assessment of Hematologic Emergencies	1099	24 Psychiatric Emergencies	1179
Scene Size-up	1099	Introduction	1180
Primary Survey	1099	Myth and Reality	1180
History Taking	1100	Defining Behavioral Emergencies	1180
Secondary Assessment	1101	The Magnitude of Mental Health Problems	1182
Reassessment	1101	Pathophysiology of Abnormal Behavior	1182
Emergency Medical Care of Hematologic Emergencies	1101	Organic Causes of Behavioral Emergencies	1182
Management of Specific Conditions	1102	Functional Disorders	1184
		Psychiatric Signs and Symptoms	1185
22 Immunologic Emergencies	1111	Patient Assessment	1186
Introduction	1112	Scene Size-up	1186
Anatomy and Physiology Review	1112	Primary Survey	1186
Anatomy Review	1112	History Taking	1190
Physiology Review	1114	Secondary Assessment	1191
Pathophysiology	1116	Reassessment	1192
Allergic Reactions Versus Anaphylaxis	1116	Emergency Medical Care	1193
Pathophysiologic Response	1117	Assessment and Management of Specific Emergencies	1194
Clinical Symptoms of Anaphylaxis	1118	Acute Psychosis	1194
Patient Assessment	1121	Suicide	1196
Scene Size-up	1121	Agitated Delirium	1197
Primary Survey	1121	Mood Disorders	1198
History Taking	1122	Neurotic Disorders	1200
Secondary Assessment	1123	Medicolegal Considerations	1202
Reassessment	1123	Consent	1203
Emergency Medical Care	1124	Limited Legal Authority	1203
Assessment and Management of Insect Stings	1128	Restraint	1203
Patient Education	1130	Posttraumatic Stress Disorder and Returning Combat Veterans	1205
		Signs and Symptoms of PTSD	1205
23 Toxicology	1137	Caring for the Combat Veteran	1206
Introduction	1138	25 Gynecologic Emergencies	1213
Types of Toxicologic Emergencies	1138	Introduction	1214
Poison Centers	1139	Anatomy and Physiology Review	1214
Pathophysiology: Routes of Absorption	1139	Anatomy Review	1214
Poisoning by Ingestion	1139	Physiology Review	1215
Poisoning by Inhalation	1140	Pathophysiology	1216
Poisoning by Injection	1141	Pelvic Inflammatory Disease	1216
Poisoning by Absorption	1142	Sexually Transmitted Infections	1217
Understanding and Using Toxidromes	1143	Vaginal Yeast Infections	1219
Overview of Substance Abuse	1143	Ruptured Ovarian Cyst	1219
Patient Assessment	1146	Ectopic Pregnancy	1219
Scene Size-up	1146	Vaginal Bleeding	1220
Primary Survey	1147	Endometritis	1220
History Taking	1148	Endometriosis	1221
Secondary Assessment	1149	Postpartum Eclampsia	1221
Reassessment	1150	Sexual Assault	1222
Emergency Medical Care	1150	Patient Assessment	1222
Pathophysiology, Assessment, and Management of Specific Poisons	1151	Scene Size-up	1222
Alcohol	1151	Primary Survey	1222
Opioids	1153	History Taking	1222
Stimulants	1155	Secondary Assessment	1225
Marijuana and Cannabis Compounds	1157	Reassessment	1226
Hallucinogens	1158	Emergency Medical Care	1226

Assessment and Management of Specific Emergencies	1227
Pelvic Inflammatory Disease	1227
Ruptured Ovarian Cyst	1227
Ectopic Pregnancy	1227
Vaginal Bleeding	1228
Sexual Assault	1228
Sexual Practices and Vaginal Foreign Bodies	1230

SECTION 8 Trauma 1237

26 Trauma Overview 1238

Introduction	1239
Energy and Trauma	1239
Mechanism of Injury Profiles	1242
Blunt and Penetrating Trauma	1242
Blunt Trauma	1243
Penetrating Trauma	1256
Blast Injuries	1258
Categories of Blast Injuries	1258
Tissues at Risk	1260
Multisystem Trauma	1261
Golden Principles of Prehospital Trauma Care	1261
Patient Assessment	1262
Injuries to the Head	1263
Injuries to the Neck and Throat	1263
Injuries to the Chest	1263
Injuries to the Abdomen	1264
Management: Transport and Destination	1264
Trauma Lethal Triad	1264
Scene Time	1265
Type of Transport	1265
Destination Selection	1266

27 Bleeding 1275

Introduction	1276
Physiology and Perfusion	1276
The Cardiac Cycle	1278
Pathophysiology	1279
External Hemorrhaging	1279
Internal Hemorrhaging	1280
The Importance of Bleeding	1282
Physiologic Response to Hemorrhaging	1282
Patient Assessment	1286
Scene Size-up	1286
Primary Survey	1287
History Taking	1288
Secondary Assessment	1289
Reassessment	1290
Emergency Medical Care	1292
External Hemorrhaging	1292
Hemorrhaging From the Nose, Ears, and Mouth	1301
Internal Hemorrhaging	1302
Management of Hemorrhagic Shock	1304

28 Soft-Tissue Injuries 1311

Introduction	1312
Anatomy and Physiology Review	1312
Skin Structure and Function	1312
Skin Tension Lines	1314
Pathophysiology of Closed and Open Injuries	1314
Closed Injuries	1314
Open Injuries	1316
Pathophysiology of Wound Healing	1319

Assessment of Closed and Open Injuries	1320
Scene Size-up	1320
Primary Survey	1321
History Taking	1321
Secondary Assessment	1322
Reassessment	1322
Emergency Medical Care of Closed and Open Injuries	1323
Closed Injuries	1323
Open Injuries	1323
Dressing and Bandaging	1324
Management of Specific Wounds	1325
Burns	1329
Pathophysiology	1329
Hypovolemic Shock	1330
Complications of Burns	1330
Burn Zone	1330
Burn Depth	1331
Burn Severity	1333
Burn Extent	1333
Assessment of Burns	1334
Scene Size-up	1334
Primary Survey	1335
History Taking	1336
Secondary Assessment	1336
Reassessment	1337
Emergency Medical Care of Burns	1339
Specific Burns and Injuries	1341

29 Face and Neck Injuries 1355

Introduction	1356
Anatomy and Physiology Review	1357
Bones and Landmarks	1357
The Eye	1358
The Ear	1359
Pathophysiology	1359
Soft-Tissue Injuries	1360
Facial Fractures	1361
Dental Injuries	1364
Patient Assessment	1364
Scene Size-up	1364
Primary Survey	1364
History Taking	1366
Secondary Assessment	1367
Reassessment	1368
Emergency Medical Care	1369
Assessment and Management of Specific Injuries	1370
Soft-Tissue Injuries	1370
Injuries of the Eyes	1371
Injuries of the Nose	1381
Injuries of the Ear	1382
Facial Fractures	1383
Oral and Dental Injuries	1384
Injuries of the Neck	1385
Laryngeal Injuries	1386
Muscular Injuries	1388
Injury Prevention	1388

30 Head and Spine Injuries 1395

Introduction	1397
Anatomy and Physiology Review	1397
The Scalp	1398
The Skull	1398
The Spine	1399
The Central Nervous System	1400
The Peripheral Nervous System	1403

Pathophysiology	1405	The Genitourinary System	1504
Head Injuries	1405	Pathophysiology	1505
Diffuse Brain Injuries	1413	General Pathophysiologic Concerns	1505
Spine Injuries	1415	Closed Abdominal Injuries	1506
Spinal Cord Injuries	1417	Open Abdominal Injuries	1508
Patient Assessment	1419	Injuries to Specific Structures	1509
Scene Size-up	1419	Patient Assessment	1514
Primary Survey	1420	Scene Size-up	1514
History Taking	1424	Primary Survey	1514
Secondary Assessment	1424	History Taking	1515
Reassessment	1427	Secondary Assessment	1516
Emergency Medical Care of TBI	1428	Reassessment	1519
Scalp Lacerations	1429	Assessment and Management of Specific Injuries	1519
Emergency Medical Care of Spinal Injuries	1430	Closed/Blunt Abdominal Injuries	1520
Immobilization of the Cervical Spine	1430	Open/Penetrating Abdominal Injuries	1521
Cervical Collars	1430	Abdominal Evisceration	1523
Preparation for Transport	1432	Kidneys	1524
Supine Patients	1433	Urinary Bladder	1524
Seated Patients	1441	External Male Genitalia	1525
Patients Wearing Helmets	1448	Female Genitalia	1526
Preferred Method	1449		
Alternate Method	1451		
Nontraumatic Spinal Conditions	1452		
31 Chest Injuries	1463	33 Orthopaedic Injuries	1531
Introduction	1464	Introduction	1532

Anatomy Review	1464	Muscles	1533
Physiology Review	1466	The Skeleton	1535
Pathophysiology	1468	Bone Classifications	1537
Signs and Symptoms of Chest Injury	1470	Typical Long Bone Architecture	1538
Patient Assessment	1471	Tendons, Ligaments, and Cartilage	1538
Scene Size-up	1471	Age-Associated Changes	1538
Primary Survey	1472	Pathophysiology	1539
History Taking	1474	Mechanism of Injury	1540
Secondary Assessment	1475	Fractures	1541
Reassessment	1477	Dislocations	1544
Emergency Medical Care	1477	Sprains	1545
Pathophysiology, Assessment, and Management		Strains	1545
of Specific Emergencies	1478	Achilles Tendon Rupture	1545
Rib Fractures	1478	Amputations	1546
Flail Chest	1479	Patient Assessment	1546
Sternal Fracture	1480	Scene Size-up	1546
Clavicle Fracture	1480	Primary Survey	1548
Commotio Cordis	1481	History Taking	1549
Simple Pneumothorax	1481	Secondary Assessment	1550
Open Pneumothorax	1483	Reassessment	1554
Tension Pneumothorax	1484	Emergency Medical Care	1554
Hemothorax	1486	Volume Deficit Due to Musculoskeletal Injuries	1555
Pulmonary Contusion	1487	Cold and Heat Application	1556
Cardiac Tamponade	1488	Splinting	1557
Myocardial Contusion	1490	Buddy Splinting	1565
Myocardial Rupture	1490	Transportation	1566
Traumatic Aortic Disruption	1490	Pathophysiology, Assessment, and Management	
Penetrating Wounds of the Great Vessels	1491	of Complications of Musculoskeletal Injuries	1567
Diaphragmatic Injury	1492	Peripheral Nerve and Vascular Injuries	1567
Esophageal Injury	1492	Compartment Syndrome	1568
Tracheobronchial Injury	1492	Crush Syndrome	1569
Traumatic Asphyxia	1493	Thromboembolic Disease	1569
		Pathophysiology, Assessment, and Management	
		of Specific Injuries	1570
32 Abdominal and Genitourinary Injuries	1501	Injuries of the Clavicle and Scapula	1570
Introduction	1502	Dislocation of the Shoulder	1572
Anatomy and Physiology Review	1502	Fracture of the Humerus	1574
Abdominal Quadrants	1502	Elbow Injuries	1574
Hollow and Solid Organs	1503	Fractures of the Forearm	1576
		Injuries of the Wrist and Hand	1577
		Fractures of the Pelvis	1577
		Dislocation of the Hip	1581

Fractures of the Proximal Femur	1582
Femoral Shaft Fractures	1584
Knee Injuries	1584
Injuries of the Tibia and Fibula	1586
Ankle Injuries	1587
Foot Injuries	1588
Amputations	1589
Sprains and Strains	1589

34 Environmental Emergencies 1597

Introduction	1599
Factors Affecting Exposure	1599
Cold Exposure	1600
Pathophysiology	1602
Assessment of Cold Injuries	1606
Scene Size-up	1606
Primary Survey	1607
History Taking	1608
Secondary Assessment	1608
Reassessment	1608
Emergency Medical Care for Cold Emergencies	1609
Withholding and Cessation of Resuscitative Efforts	1611
Emergency Medical Care of Local Cold Injuries	1612
Cold Exposure and You	1613
Heat Exposure	1613
Pathophysiology	1613
Assessment of Heat Injuries	1616
Scene Size-up	1616
Primary Survey	1616
History Taking	1617
Secondary Assessment	1617
Reassessment	1618
Emergency Medical Care for Heat Emergencies	1618
Heat Cramps	1618
Heat Exhaustion	1618
Heatstroke	1620
Water Emergencies	1621
Drowning	1621
Diving Emergencies	1622
General Pathophysiology: Physical Principles of Pressure Effects	1622
Water Rescue	1628
Spinal Injuries in Submersion Incidents	1629
Recovery Techniques	1631
Assessment of Drowning and Diving Emergencies	1631
Scene Size-up	1631
Primary Survey	1632
History Taking	1633
Secondary Assessment	1633
Reassessment	1634
Emergency Care for Drowning or Diving Emergencies	1634
Submerged Vehicle Incidents	1634
Other Water Hazards	1635
Prevention	1635
High Altitude	1635
Lightning Injuries	1636
Emergency Medical Care for Lightning Injuries	1638
Bites and Envenomations	1639
Spider Bites	1639
Hymenoptera Stings	1641

Snakebites	1641
Scorpion Stings	1646
Tick Bites	1646
Injuries From Marine Animals	1647

SECTION 9 Special Patient Populations 1655

35 Obstetrics and Neonatal Care 1656

Introduction	1658
Anatomy and Physiology Review: The Female Reproductive System	1658
Gestation	1659
Normal Maternal Changes of Pregnancy	1661
Pathophysiology During Pregnancy	1663
Abortion	1663
Ectopic Pregnancy	1664
Third-Trimester Bleeding	1664
Bleeding and the Placenta	1665
Hypertensive Disorders	1666
Effects of Substance Abuse	1667
Isoimmunization (Rh Sensitization)	1667
Gestational Diabetes	1667
Hyperemesis Gravidarum	1668
Premature Rupture of Membranes	1668
Effects of Physical Abuse	1668
Special Considerations for Trauma and Pregnancy	1668
Assessment and Treatment of the Pregnant Trauma Patient	1670
Maternal Cardiac Arrest	1671
Cultural Value Considerations	1671
Teenage Pregnancy	1671
Patient Assessment	1672
Scene Size-up	1672
Primary Survey	1672
History Taking	1673
Secondary Assessment	1675
Reassessment	1676
Assessment and Management of Nondelivery Emergencies	1676
Spontaneous Abortion	1676
Third-Trimester Bleeding	1677
Ectopic Pregnancy	1678
Preeclampsia	1678
Supine Hypotensive Syndrome	1678
Gestational Diabetes	1678
Normal Childbirth	1679
Stages of Labor	1679
Preparing for Delivery	1679
Delivering the Newborn	1681

COVID-19 Disclaimer

At the time of this edition's development, we find ourselves in the middle of a 100-year event: the COVID-19 pandemic. Although we are perhaps more mindful than ever of the importance of personal protective equipment (PPE) in our profession, readers will still notice some variability throughout this textbook with regard to the types of PPE worn by EMS providers and others as they care for patients. They may also question the inclusion of skills and techniques that are discouraged in the context of COVID-19. There are several explanations for these inconsistencies.

Prior to 2020, the level of PPE commonly worn by all providers during patient encounters typically included gloves. Eye protection was added during situations in which the risk of a splash was high or when there was significant risk of aerosolization of material that could potentially come in contact with the eyes. For example, eye protection was typically worn while caring for patients who were bleeding significantly, when performing airway-related procedures, and during maternity calls. It was added on calls when there was a perceived high risk of being splashed with a potentially contaminated body fluid. In the COVID-19 era and beyond, however, use of eye protection has become more common.

In addition, masks are now standard equipment for all interpersonal encounters, not just patient

encounters. At various times throughout the pandemic, masks have been required in public places, such as grocery stores. Simple face masks or cloth masks decrease the risk of infection for the person wearing the mask and decrease the risk associated with viral shedding that is a known consequence of infection, even in asymptomatic hosts. In other words, people without symptoms can still be infected with the virus and thus transmit it to others. Asking everyone to wear a mask in public can make the environment safer.

Furthermore, it is recommended that providers caring for COVID-19 patients or those who have overt symptoms such as fever or cough wear a higher level of protection, such as an N95 respirator. There is variability in that recommendation also, as many agencies are using N95 respirators for all patient encounters, given the increased level of protection afforded and the pervasiveness in the population of asymptomatic individuals who could transmit the disease.

We have tried throughout the text to apply the best current knowledge and practices available. However, that science is developing rapidly, as is clinical practice. Some information in this textbook relating to PPE recommendations may become outdated in the coming years. We will attempt to make supplemental material available that reflects the most updated knowledge.

Chapter 1

EMS Systems

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Preparatory

Applies fundamental knowledge of the EMS system, safety/well-being of the AEMT, medical/legal and ethical issues to the provision of emergency care.

EMS Systems

- EMS systems (p 3)
- History of EMS (pp 7–8)
- Roles/responsibilities/professionalism of EMS personnel (p 8)
- Quality improvement (p 18)
- Patient safety (pp 18–19)

Research

- Impact of research on emergency medical responder (EMR) care (p 12)
- Data collection (pp 13–15)
- Evidence-based decision making (p 24)

Public Health

Uses simple knowledge of the principles of the role of EMS during public health emergencies.

KNOWLEDGE OBJECTIVES

1. Define emergency medical services (EMS). (p 3)
2. Discuss the four levels of EMS training and licensure. (p 4)
3. Describe licensure criteria for advanced emergency medical technicians (AEMTs). (pp 6–7)
4. Describe how the Americans with Disabilities Act (ADA) applies to employment as an AEMT. (p 7)
5. Discuss the history of the development of the EMS system. (pp 7–8)
6. Describe the levels of EMS training in terms of skill sets needed for each of the following: emergency medical responder (EMR), emergency medical technician (EMT), AEMT, and paramedic. (pp 8–11)
7. Discuss the possible presence of other responders at a scene with EMR training, some knowledge of first aid, or merely good intentions, and their need for direction. (pp 12–13)
8. Describe the components of the EMS system. (pp 13–16)
9. Describe how medical direction of an EMS system works and your role in the process. (pp 16–17)
10. Describe the goals of Mobile Integrated Healthcare (MIH) and community paramedicine. (p 18)
11. Discuss the purpose of the EMS continuous quality improvement (CQI) process. (p 18)
12. Describe ways to limit or eliminate human error and improve patient safety. (pp 18–19)
13. Characterize the EMS system's role in prevention and public education in the community. (pp 21–22)
14. Discuss the signs of human trafficking that you may encounter during an emergency response. (p 23)

PHOTO: © mikedray/Shutterstock.

15. Describe situations in which transport to a specialty center is warranted. (pp 24–25)
16. Describe your roles and responsibilities as an AEMT. (pp 25–26)

17. Describe the attributes you are expected to possess. (p 26)
18. Discuss the impact of the Health Insurance Portability and Accountability Act (HIPAA) on patient privacy. (p 27)

SKILLS OBJECTIVES

There are no skills objectives for this chapter.

Introduction

This textbook is designed to serve as the text and primary resource for the advanced emergency medical technician (AEMT) course. This chapter describes the content and objectives of the AEMT course. It discusses what is expected of you during the course and what other requirements you need to meet to be licensed or certified as an AEMT in most states.

Emergency medical services (EMS) is a multidisciplinary system of professionals and agencies working together to provide prehospital emergency care to sick and injured people. This chapter overviews the different types of providers and the different levels of care that compose this system. It also discusses administration, medical direction, quality control, and regulation of EMS systems. The chapter concludes with a detailed discussion of the roles and responsibilities of AEMTs as health care professionals.

Course Description

As an AEMT, you will be a critical part of the EMS system and will play a significant role in your patients' lives (**FIGURE 1-1**). Although not every call for care will involve a life-threatening emergency, the compassion, professionalism, and skill you bring will have a tremendous positive impact on each patient you encounter.

Each emergency medical service is part of a local or regional EMS system that provides the prehospital and hospital components required for the delivery of proper emergency medical care. The standards for prehospital emergency care and the people who provide it are governed by the laws in each state and are typically regulated by a state office of EMS.

The people who provide emergency medical care in the field are trained and, except for licensed

FIGURE 1-1 As an AEMT, you will be part of a larger team that responds to a variety of calls and provides a wide range of prehospital emergency care.

© John Moore/Staff/Getty Images News/Getty Images.

physicians, must be either certified EMS personnel or state-licensed. A **certification** exam is used to ensure all health care providers have at least the same basic level of knowledge and skill. These exams are typically conducted or regulated by a state or military agency or by the National Registry of Emergency Medical Technicians (NREMT). The NREMT is a nongovernmental, not-for-profit organization whose mission is to provide a valid, uniform process to assess the knowledge, skills, and abilities (KSAs) for competent EMS practice. Almost all states require NREMT certification for candidates to be eligible for a license to practice. After you pass this exam, you are eligible to apply for state licensure.

Licensure is the process by which states ensure applicant competency in an examination setting. This allows states to manage who can function as a health care provider. The ways in which these terms are used may vary by state. For the purpose of this textbook, the term *licensure* will be used.

Obtaining licensure in a state does not grant an AEMT an unrestricted right to practice. The

Words of Wisdom

Although not all states use the NREMT testing process, EMS certification exams may be informed by the NREMT's EMS Practice Analysis. Approximately every 5 years, the NREMT surveys EMS providers of all levels from across the United States to understand the current real-world practice of prehospital emergency care and to help create a blueprint for valid certification exams. In 2019, the Practice Analysis also pulled data from the National EMS Information System (NEMSIS) to get a real picture of the types of calls and interventions EMS personnel in the United States encounter in actual practice. In effect, the Practice Analysis attempts to answer the question, "What is most important for EMS providers to know and be able to do to deliver safe and effective care?" From this information, the current Practice Analysis determines the certification test plan for each level of EMS provider. The test plan lays out an approximate percentage of questions on each topic that students will encounter on NREMT certification exams.

next phase of becoming a health care provider is **credentialing**. Credentialing is the verification process of a health care provider's qualifications. Credentialing may be a local or regional process, and it is typically directed and overseen by a physician medical director. In some cases, AEMTs may be specifically credentialed to perform either fewer or additional techniques in their area or to work in certain types of care systems.

In most states, providers are categorized into four different training and licensure levels:

emergency medical responder (EMR), **emergency medical technician (EMT)**, **advanced emergency medical technician (AEMT)**, and **paramedic**.

TABLE 1-1 shows some of the responsibilities and requirements of these roles. The **National EMS Scope of Practice Model** describes the four levels of EMS practice. The National EMS Education Standards outline the knowledge and competencies that should be taught to students in each of these four levels of EMS practice. This education incorporates all the KSAs needed to become a competent entry-level AEMT. For any role in emergency services and health care, education must continue throughout the provider's career.

Words of Wisdom

In some states, AEMT is the introductory level and may not require prerequisites.

Although the specific training and licensure requirements vary from one state to another, almost every state's requirements follow or exceed the guidelines recommended in the current National Highway Traffic Safety Administration (NHTSA) EMS Education Standards. In the United States, NHTSA is the federal administrative source for education standards and related documents.

This textbook covers the practice and skills identified in the 2021 *National EMS Education Standards*. It also covers the information required for AEMTs to perform the skills outlined in the 2019 National EMS Scope of Practice Model.

TABLE 1-1 EMS Responsibilities and Requirements

Training/Licensure Level	Responsibilities and Requirements ^a
Emergency medical responder (EMR)	First medically trained professional to arrive on scene; provides initial care before the ambulance arrives; assists more-advanced responders
Emergency medical technician (EMT)	Trained in basic life support (BLS) , including the use of automated external defibrillators and airway adjuncts; assists with administering certain medications
Advanced emergency medical technician (AEMT)	Advanced training in specific aspects of advanced life support (ALS) (eg, intravenous [IV] therapy); administers certain emergency medications and certain types of advanced airway management
Paramedic	Trained in ALS, endotracheal intubation, emergency pharmacology, cardiac monitoring, and other advanced assessment and emergency medical treatment skills

a: Responsibilities and requirements vary by state.

Words of Wisdom

Individual states have the option to allow providers to perform certain skills outside of the National EMS Scope of Practice.

In addition to the required core content, this text includes additional information to help you understand and apply the material and skills included in the AEMT course.

Words of Wisdom

Study Tips for Using This Text

Complete each assignment diligently and carefully.

Read the textbook like a textbook, not like a blog, magazine, or novel.

Read each chapter several times, and underline key points. Take notes!

Note the chapter's objectives so you can effectively measure your knowledge.

Ask your instructor to clarify any questions you have.

Take additional notes when the assigned material is expanded on in class.

Use supporting materials (eg, assessments, animations, videos, and workbooks) to enhance your learning experience.

Remember: The only dumb question is the one you fail to ask.

AEMT Training: Focus and Requirements

As an AEMT, some of the patients you treat will have life-threatening conditions, whereas others require only supportive care. The skills needed to safely deliver this care are found within this textbook. Some

of the main subjects that will be discussed include the following:

- **Scene size-up.** During scene size-up, you must gain a big-picture perspective of the call, determine if it is safe to proceed, determine whether additional resources are needed, and identify the initial approach to mitigate the emergency scene. EMS operates in a wide variety of environments that can create situations where EMS personnel can be injured. A primary role of any EMS provider is to ensure personal safety.
- **Patient assessment.** Patient assessment is the foundation of any EMS call. You must determine what is wrong with the patient. Patients can have many complaints, and you will learn to determine which complaints are life threatening.
- **Treatment.** As an AEMT, ensure the patient is oxygenated, administer certain medications, and administer IV therapy if needed. Control bleeding and assist patients during childbirth. In addition to hands-on skills, you will learn how to manage patients who are in emotional crisis and to calm patients and relieve some of their anxieties.
- **Packaging.** In EMS, packaging refers to the act of preparing a patient for movement as a unit by means of a backboard or similar stabilization device. Most patients need to be transported to a facility. This could mean a hospital, clinic, or other medical care facility. You will learn how to transport patients with a wide variety of illnesses and injuries.
- **EMS as a career.** Many of you are taking this course because you want to help people. To ensure all EMS providers have a long, healthy career, it is important for you to learn how to take care of yourself. We will discuss job stressors and successful ways to cope with stress.

YOU are the Provider

Part 1

You were just hired as an AEMT and report to your first day on the job with the local ambulance service. As you begin your orientation, the EMS director asks you two initial questions:

1. What is emergency medical services (EMS)?
2. Why was the National Registry of Emergency Medical Technicians (NREMT) established?

Words of Wisdom

The Star of Life

The NHTSA recognized the need for a symbol that would represent EMS as a critical public service and created the *Star of Life*. NHTSA holds priority rights to the use of this registered certification mark.

Adapted from the personal Medical Identification Symbol of the American Medical Association, each bar on the Star of Life represents an EMS function:

1. Detection
2. Reporting
3. Response
4. On-scene care
5. Care in transit
6. Transfer to definitive care

The serpent and staff in the symbol portray the staff of Asclepius, an ancient Greek god of medicine. Overall, the staff represents medicine and healing, with the skin-shedding serpent being indicative of renewal.

The Star of Life has become synonymous with emergency medical care around the globe. This symbol can be seen as a means of identification on ambulances; emergency medical equipment; patches or apparel worn by EMS providers; and materials such as books, pamphlets, manuals, reports, and publications that either have a direct application to EMS or were generated by an EMS organization. It also appears on road maps and highway signs indicating the location of or access to qualified emergency medical care.

Adapted from US National Highway Traffic Safety Administration. <http://www.ems.gov>.

- Successful completion of a background check and drug screening
- Valid driver's license
- Successful completion of a recognized health care provider's basic life support (BLS)/cardio-pulmonary resuscitation (CPR) course
- Successful completion of a state-recognized AEMT course
- Successful completion of a state-recognized written certification examination
- Successful completion of a state-recognized practical certification examination
- Demonstration that you can meet the psychological and physical criteria necessary to perform safely and properly all the tasks and functions described in the defined role of an AEMT
- Compliance with other state, local, and employer provisions

The state-recognized written and practical examination may be the NREMT Exam based on the individual state. The NREMT was established in 1970 to certify and register EMS professionals through a valid and uniform process that assesses their knowledge and skills to ensure competent practice. The NREMT requires recertification every 2 years to ensure continued competence. Because most states now recognize NREMT certification, it is easy for an AEMT to move to another state and continue to work without attending another course and taking another certification exam for that area. If you move to a different state, you may be allowed to apply for reciprocity rather than starting your

Licensure Requirements

To be recognized and to function as an AEMT, you must meet certain requirements. The specific requirements differ from state to state. Ask your instructor or learning institute, or contact your state EMS official to find out about the requirements in your state. Generally, the criteria to be licensed and employed as an AEMT will include the following:

- High school diploma or equivalent
- Proof of immunization against certain communicable diseases

Words of Wisdom

In 2020, the NREMT launched the National EMS-ID number system. An EMS-ID is a 12-digit identification number issued at no charge to all EMS professionals, from EMR to paramedic, and to students entering the profession. The number is automatically generated by the National Registry when a person creates an account. For EMS providers with an existing account, an EMS-ID is retroactively created. Unlike the number issued by the National Registry (NR Number) when an individual becomes certified, EMS-IDs do not change as the person's certification level changes. Thus, the various certification numbers professionals may obtain in their career are all tied back to the single EMS-ID.

training all over or taking the new state's certification exam. **Reciprocity** is the recognition by one state of another state's licensure, allowing a health care professional from another state to practice in the new state.

The **Americans With Disabilities Act (ADA)** of 1990 protects people who have a disability from being denied access to programs and services that are provided by state or local governments and prohibits employers from failing to provide full and equal employment to people with disabilities. In addition, Title I of the ADA protects those with disabilities seeking gainful employment under many circumstances. Employers with 15 or more employees are required to adjust processes so a candidate with a disability can be considered for the position and, when possible, to modify the work environment or how the job is normally performed.¹ This allows many people who can perform the functional job skills the opportunity to pursue a career in EMS. To obtain further information about the Americans with Disabilities Act and employment as an AEMT, contact your state EMS office.

One of the primary responsibilities of each state is to ensure the safety of its residents. As such, states have requirements prohibiting people with certain legal infractions from becoming EMS providers. The specific legal exclusions vary from state to state. States may exclude from certification persons with a history of a health problem that could make their performance of AEMT tasks dangerous to themselves or others. Contact your state EMS official for more information.

Overview of the EMS System

History of EMS

As an AEMT, you will join a long tradition of people who have provided emergency medical care to their fellow human beings. Early efforts to systematize prehospital care include the field treatments and transport innovated during the Civil War. Civilian ambulatory services soon followed. With the use of motor vehicles in warfare, volunteer ambulance squads were organized and went overseas to provide care for the wounded in World War I. In World War II, the military trained special corpsmen to provide care in the field and bring the casualties to aid stations staffed by nurses and physicians. In the Korean conflict, the care system evolved to the field medic and rapid helicopter evacuation to nearby

Mobile Army Surgical Hospital units, where immediate surgical intervention was provided. Many advances in the immediate care of trauma patients resulted from the casualty experiences in the Korean and Vietnam conflicts. More recent military engagements, such as conflicts in the Middle East, and responses to terrorism continue to influence EMS practices.

Unfortunately, emergency medical care of people injured and ill at home or elsewhere outside a hospital had not progressed to a similar level. As late as the early 1970s, emergency ambulance service and care across the United States varied widely. In some places, care was provided by well-trained, advanced first aid squads that had well-equipped, modern ambulances. In a few urban areas, it was provided by hospital-based ambulance services that were staffed with interns and early forms of prehospital care providers. In many places, the only emergency medical care and ambulance service was provided by the local funeral home using a hearse that could be converted to carry a cot and serve as an ambulance. In other places, the police or fire department used a station wagon that carried a cot and a first aid kit. In most cases, both were staffed by a driver and an attendant who had some first aid training. In the few areas where a commercial ambulance was available to transport ill and injured people, it was usually similarly staffed and served primarily to transport the patient to the hospital.

Words of Wisdom

As an AEMT, you will continue a long tradition of people who have provided emergency medical care to their fellow human beings. The AEMT is an important contributor to the overall health care community and ultimately helps reduce mortality and morbidity.

Many communities had no formal provision for prehospital emergency care or transportation. Injured people were given first aid by police or fire personnel at the scene and were transported to the hospital in a police or fire officer's car. Customarily, patients with an acute illness were transported to the hospital by a relative or neighbor and were met by their family physician or an on-call hospital physician who assessed them and then summoned any specialists and operating room staff who were

needed. Except in large urban centers, most hospitals did not have the staffed emergency departments (EDs) that we are accustomed to today.

EMS as we know it today had its origins in 1966 with the publication of *Accidental Death and Disability: The Neglected Disease of Modern Society*. This report, known more commonly as The White Paper, prepared jointly by the Committees on Trauma and Shock of the National Academy of Sciences/National Research Council, revealed to the public and Congress the serious inadequacy of prehospital emergency care and transportation in many areas.

As a result, Congress mandated that two federal agencies address these issues. The NHTSA of the Department of Transportation (DOT), through the Highway Safety Act of 1966, and the Department of Health, Education, and Welfare (now known as the Department of Health and Human Services), through the Emergency Medical Services Development Act of 1973, created funding sources and programs to develop improved systems of prehospital emergency care.² They also required states to focus on EMS personnel training and the legislation and regulation of EMS personnel levels.

In the early 1970s, the DOT developed and published the first National Standard Curriculum to serve as the guideline for the training of EMTs.³ To support the EMT course, the American Academy of Orthopaedic Surgeons prepared and published the first EMT textbook—*Emergency Care and Transportation of the Sick and Injured*—in 1971. This textbook is the AEMT adaptation of that publication. Through the 1970s, following the recommended guidelines, each state developed the necessary legislation, and the EMS system was developed throughout the United States. During this same period, emergency medicine became a recognized emergency medical specialty, and fully staffed EDs became the accepted standard of care.

In the late 1970s, the DOT developed a recommended National Standard Curriculum for the training of paramedics and identified a part of the course to serve as training for AEMTs.

During the 1980s, many areas enhanced the EMS National Standard Curriculum by adding providers with higher levels of training who could provide key components of advanced life support (ALS) care. The availability of paramedics and ALS-level care on calls that require or benefit from advanced care has grown steadily in recent years.

In addition, with the evolution in training and technology, EMTs and AEMTs can now perform several important advanced skills in the field that were formerly reserved for paramedics.

This growth and sophistication of the EMS system did not come without drawbacks. As each state sought to create a system that would meet the needs of its citizens, the roles and responsibilities of EMS providers began to vary from state to state. For example, in some states, EMTs were allowed to administer medications; in other states they were not.

In the 1990s, NHTSA began an examination of EMS from a national perspective. With the counsel of EMS providers, physicians, fire chiefs, nurses, state administrators, educators, and other interested professionals, NHTSA created the *EMS Agenda for the Future*. This important document creates a plan to standardize the levels of EMS education and EMS providers in an effort to ensure a more seamless delivery of EMS care across the United States. In 2019, NHTSA revised this document and published *EMS Agenda 2050*. This revision places greater emphasis on patient-centered care in hopes of better attending to the patient's perspective and meeting the needs of patients' loved ones, communities, and the clinicians who provide care.

The skills you learn and the scope of practice that AEMTs now enjoy are part of this national movement toward an EMS system that meets the needs of an ever-changing health care industry and meets those needs through a safe and efficient method.

Levels of Training

As discussed earlier, licensure of AEMTs is a state function, subject to the laws and regulations of the state in which the AEMT practices. Each state is granted the ability to control the functions of its licensed providers. For this reason, there remains some variation from state to state on the scope of AEMT practice, as well as training and recertification requirements. Here is how the system is supposed to work from the federal level down to the local level.

At the federal level, NHTSA brought in experts from around the United States to create the National EMS Scope of Practice Model. This document provides overarching guidelines for the minimum skills each level of EMS providers should be able to perform. **TABLE 1-2** shows the guidelines from

that model. Some items in the table are flagged, and corresponding notes are provided to show areas where current practice has evolved. For example, certain skills listed in the table are no longer

practiced or have been aligned with a different skill level. Because licensure is a state function, at the state level laws are enacted to regulate how EMS providers will operate and are then executed by the

TABLE 1-2 The Interpretive Guidelines: National EMS Scope of Practice Model

An EMT also provides the skills listed in the EMR level.

An AEMT also provides the skills listed in the EMR and EMT levels.

A paramedic also provides the skills listed in the EMR, EMT, and AEMT levels.

EMR	EMT	AEMT	Paramedic
Airway and Breathing Minimum Psychomotor Skill Set			
Oral airway	Humidifiers	Supraglottic airway	BPAP/CPAP
Bag-mask device	Partial rebreathing mask		Needle chest decompression
Sellick maneuver ^a	Venturi mask		Chest tube monitoring
Head tilt–chin lift	Manually triggered ventilators		Percutaneous cricothyrotomy
Jaw-thrust maneuver	Automatic transport ventilators		ETCO ₂ /capnography
Modified chin lift	Oral and nasal airways		NG/OG tube
Obstruction, manual			Nasal and oral endotracheal intubation
Oxygen therapy			Airway obstruction removal by direct laryngoscopy
Nasal cannula			Positive end-expiratory pressure
Nonrebreathing mask			
Upper airway suctioning			
Assessment Minimum Psychomotor Skill Set			
Manual BP	Pulse oximetry	Blood glucose monitoring ^b	ECG interpretation
	Manual and automatic BP		Interpretive 12-lead
			Blood chemistry analysis
Pharmacologic Intervention Minimum Psychomotor Skill Set			
Medication Administration Routes	Assisted Medications		
Unit dose auto-injector for self or peer care (MARK 1)^c	Assisting a patient in administering their own prescribed medications, including auto-injector	- Peripheral IV insertion - IV fluid infusion - Pediatric IO insertion	- Central line monitoring - IO insertion - Venous blood sampling

(continues)

TABLE 1-2 The Interpretive Guidelines: National EMS Scope of Practice Model (*continued*)

EMR	EMT	AEMT	Paramedic
	Medication Administration Routes • Buccal • Oral	Medication Administration Routes • Aerosolized • Subcutaneous • IM • Nebulized • SL • IN • IV push for D₅₀ and narcotic antagonist only	Medication Administration Routes • Endotracheal • IV (push and infusion) • NG • Rectal • IO • Topical • Accessing implanted central IV port
	Medications to Be Administered • Physician-approved over-the-counter medications (oral glucose, aspirin for chest pain or suspected ischemic origin)	Medications to Be Administered • SL nitroglycerin for chest pain of suspected ischemic origin • Subcutaneous^d and IM epinephrine for anaphylaxis • Glucagon and IV D₅₀ for hypoglycemia • Inhaled beta agonist for dyspnea and wheezing • Narcotic antagonist • Nitrous oxide for pain relief	Medications to Be Administered • Physician-approved medications • Maintenance of blood administration • Initiation of thrombolytics
Emergency Trauma Care Minimum Psychomotor Skill Set			
Manual cervical stabilization	Spinal motion restriction		Morgan lens
Manual extremity stabilization	Seated spinal motion restriction		
Eye irrigation	Long backboard		
Direct pressure	Extremity splinting		
Hemorrhage control	Traction splinting		
Emergency moves for endangered patients	Mechanical patient restraint		
	Tourniquet ^e		
	MAST/PASG ^f		
	Cervical collar		
	Rapid extrication		

EMR	EMT	AEMT	Paramedic
Medical/Cardiac Care Minimum Psychomotor Skill Set			
CPR	Mechanical CPR		Cardioversion
AED	Assisted complicated delivery of an infant		Carotid massage
Assisted normal delivery of an infant			Manual defibrillation
			TC pacing

Abbreviations: AED, automated external defibrillator; AEMT, advanced emergency medical technician; BPAP, bilevel positive airway pressure; BP, blood pressure; CPAP, continuous positive airway pressure; CPR, cardiopulmonary resuscitation; D₅₀, 50% dextrose; ECG, electrocardiogram; EMR, emergency medical responder; EMT, emergency medical technician; ETCO₂, end-tidal carbon dioxide; IM, intramuscular; IN, intranasal; IO, intraosseous; IV, intravenous; MAST, military antishock trousers; NG, nasogastric; OG, orogastric; PASG, pneumatic antishock garments; SL, sublingual; TC, transcutaneous

Note: The 2019 National EMS Scope of Practice Model serves as a foundation for states to build their own model. It is intended to illustrate the operation of each level of EMS provider and the progression from one level to another. It is not inclusive of every skill a state may allow.

^aThe Sellick maneuver is no longer recommended.

^bBlood glucose monitoring is now considered an EMT-level skill.

^cMark 1 has been replaced by the DuoDote and the Antidote Treatment Nerve Agent Auto-Injector (ATNAA).

^dSubcutaneous epinephrine administration is typically considered a paramedic-level skill now.

^eTourniquet use has evolved to be practiced by all providers, including the EMR level.

^fMAST/PASG has very specific indications, including stabilizing bilateral femur fractures or pelvic fractures. See Chapter 27, Bleeding, for further information.

© Jones & Bartlett Learning.

state-level EMS administrative offices that control licensure. Finally, the local medical director decides the day-to-day limits of EMS personnel. For example, the medications that will be carried on an ambulance or where patients are transported are the day-to-day operational concerns about which the medical director will have direct input.

The national guidelines are intended to create more consistent delivery of EMS across the United States. A medical director can allow an AEMT to perform a skill only if the state has already approved performance of that skill. The medical director can limit the scope of practice but cannot expand it beyond state law. Expanding the scope of practice requires state approval.

The EMT, AEMT, and paramedic education standards and instructional guidelines can be downloaded from www.ems.gov. In addition, the NREMT is a nongovernmental agency that provides national standardized testing for EMS certification in much of the United States. Many states use the

National Registry standards to certify their AEMTs and grant licensing reciprocity to NREMT-certified AEMTs. However, it is important to remember EMS is regulated entirely by the state in which you are licensed.

Public Basic Life Support and Immediate Aid

With the development of EMS and increased awareness of the need for immediate emergency medical care, millions of laypeople have been trained in BLS/CPR. In addition to CPR, many people have taken short basic first aid courses that include control of bleeding and other simple skills that may be required to provide immediate essential care. These courses are designed to train people so that people in the workplace, such as teachers, coaches, babysitters, and others, can provide the necessary critical care in the minutes before AEMTs or other responders arrive at the scene.

One of the most dramatic recent developments in prehospital emergency care is the use of an **automated external defibrillator (AED)**. These remarkable devices, some no larger than a cell phone, detect treatable life-threatening cardiac dysrhythmias (ventricular fibrillation and ventricular tachycardia) and deliver the appropriate electrical shock to the patient. Designed to be used by an untrained layperson, they are now included at every level of prehospital emergency training.

Emergency Medical Responder

Because the presence of a person who is trained and able to initiate BLS and other urgent care cannot be ensured, the EMS system includes immediate care by EMRs, such as law enforcement officers, firefighters, park rangers, ski patrollers, or other organized rescuers who often arrive at the scene before the ambulance and providers (**FIGURE 1-2**). EMR training provides these people with the skills necessary to initiate immediate care and then assist

FIGURE 1-2 Emergency medical responders, such as law enforcement officers, are trained to provide immediate basic life support until providers arrive on the scene.

Courtesy of Captain David Jackson, Saginaw Township Fire Department.

other EMS providers on their arrival. The course focuses on providing immediate BLS and urgent care with limited equipment. It also familiarizes students with the additional procedures, equipment, and packaging techniques that other EMS providers may use and with which the EMR may be called on to assist.

Emergency Medical Technician

The EMT course requires a minimum of 150 hours of instruction and provides the essential knowledge and skills required to provide basic emergency medical care in the field. The course serves as the foundation on which additional knowledge and skills are built in AEMT training. On arrival at the scene, you and the other providers who have responded with the ambulance should assume responsibility for the assessment and care of the patient, followed by proper packaging and transport of the patient to the ED if appropriate.

Street Smarts

In addition to professional EMRs, AEMTs often encounter a variety of people on the scene eager to help. You will encounter Good Samaritans trained in first aid and CPR, physicians and nurses, and other well-meaning people with or without prior training and experience. If identified and used properly, these people can provide valuable assistance when you are short-handed. At other times, they can interfere with operations and even create problems or a danger to themselves or others. It will be your task in your initial scene size-up to identify the various people on the scene and orchestrate well-meaning attempts to assist.

YOU are the Provider

Part 2

The director continues to explain that the service uses the National EMS Scope of Practice Model as the framework for what its providers can do in the field. He also mentions that the local 9-1-1 center hires only dispatchers who have completed the Emergency Medical Dispatch (EMD) course.

3. What is the National EMS Scope of Practice Model?
4. How does the EMD system work?

FIGURE 1-3 AEMTs have EMT training and various advanced skills such as performing intravenous therapy.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Advanced Emergency Medical Technician

The AEMT course and training are designed to add knowledge and skills in specific aspects of ALS to providers who have been trained and have experience in providing emergency medical care as EMTs. Additional skills above the EMT level include IV therapy, use of advanced airway adjuncts, and the knowledge and skills necessary for the administration of a limited number of medications (**FIGURE 1-3**). The AEMT course is a minimum of 200 hours beyond EMT requirements. The purpose of this level of EMS provider is to deliver an expanded range of skills beyond the EMT. In some parts of the United States, the availability of paramedics is limited. AEMTs help to fill the gap by providing limited ALS care to regions where paramedics are not available.

Paramedic

The paramedic has completed an extensive course of training that substantially increases knowledge and mastery of basic skills and covers a wide range of ALS skills. This curriculum ranges approximately 800 to 1,100 hours beyond EMT requirements, usually equally divided between classroom and internship training. Increasingly, this training is offered within the context of an associate or bachelor's degree college program.

Components of the EMS System

EMS Agenda 2050 is a multidisciplinary, national review of all aspects of EMS delivery. The goal is

TABLE 1-3 EMS Agenda 2050 Components of an EMS System

A People-Centered EMS System

1. Comprehensive, quality, convenient care
2. Evidence-based clinical care
3. Efficient, well-rounded care
4. Preventive care
5. Comprehensive and easily accessible patient records

© Jones & Bartlett Learning.

to develop a more cohesive and consistent system across the country. The document features five key aspects of a people-centered EMS system, as outlined in **TABLE 1-3**.

The vision of EMS Agenda 2050 is that a people-centered EMS system is one in which people receive comprehensive, quality care in the most comfortable and convenient place. This care is based on sound research focused on producing the right outcomes. In this people-centered system, patients who need it will receive transport that is safe and efficient (not necessarily at a high rate of speed or with lights and siren). Care in a people-centered system will focus not only on life-saving interventions, but also on reducing physical, emotional, and psychological suffering. Such EMS systems will be an integrated part of a larger health care system focused on proactively preventing injuries and illnesses rather than reactively responding to treat them. EMS clinicians will have access to and be able to contribute to a patient's comprehensive medical record, allowing not only improvements of treatment for individual patients, but also updates in prevention, diagnosis, and treatments as our understanding and technology advance.

The EMS Agenda 2050 guiding principles include an EMS system with the following characteristics:

- Inherently safe and effective, so the entire system from start to finish is designed to minimize exposure to injury, infections, illness, or stress
- Integrated and seamless, where EMS is fully integrated with all other aspects of health care and is engaged with other emergency services

and within the communities in which they operate

- Reliable and prepared, ensuring EMS care is delivered consistently and compassionately and is guided by sound research at all times, by all EMS providers, at all levels, or from all agencies
- Socially equitable, so that access to care and the quality of care are not determined by a patient's age, socioeconomic status, gender, ethnicity, or where they live
- Sustainable and efficient, meaning systems must be fiscally responsible, providing value to the community with a minimum of waste and a maximum of accountability
- Adaptable and innovative, evolving to meet the changing needs of the people whom they serve by continuously evaluating new tools and techniques, education programs, and system designs

Public Access

Easy access to help in an emergency is essential. In most of the United States, an emergency communications center that dispatches fire, police, rescue, and EMS units can be reached by dialing 9-1-1. At the communications center, trained dispatchers obtain the necessary information from the caller and, following dispatch protocols, dispatch the ambulance crew and other equipment and responders who might be needed. This communications center is called a **public safety access point**, or sometimes public safety answering point.

In an enhanced 9-1-1 system, the address of the caller is displayed on a screen. The address remains on the screen until the dispatcher releases it so that if the caller is unable to speak or hangs up, the caller's location remains displayed. Most emergency communications centers also include special equipment that allows people with speech or hearing disabilities to communicate with the dispatcher via a keyboard and printed messages. In some areas, rather than 9-1-1, a different special published emergency number may be used to call for EMS. Social media may play an evolving role in allowing laypeople trained in CPR to be alerted of a cardiac arrest in their area. Training the public in how to summon an EMS unit is an important part of the public education responsibility of each EMS service.

Enhanced 9-1-1 systems for cell phones are now available that identify not only the cellular phone number from which an emergency call is being placed, but also the exact geographic coordinates of the phone at the time the call is made. Such systems use GPS (global positioning system) technology. Because cell phones capable of transmitting a GPS signal and a system capable of receiving that signal are both required, the technology will require additional time and resources to implement.

A system called **emergency medical dispatch (EMD)** was developed to assist dispatchers in providing callers with vital instructions to help them manage medical emergencies until EMS crews arrive. Dispatchers are trained and provided with scripts to help them relay relevant instructions to callers. The system helps dispatchers select appropriately resourced units to respond to a request for assistance. It is the dispatcher's duty to relay all relevant and available information to the responding crews in a timely manner. Keep in mind, however, current technology does not allow the dispatcher to see what is actually occurring at the scene and that it is not uncommon for you to find the reality of the call quite different from the dispatch information. The dispatchers can relay only the information provided to them by the caller.

Communication Systems

With the information provided by the caller, the dispatcher will select the appropriate parts of the emergency system that need to be activated. According to the National Fire Protection Association, 45% of fire departments nationwide provide BLS care and 17% of fire departments provide ALS care. Nationwide, 38% of fire departments do not provide emergency medical services.⁴

In most municipalities, EMS is a part of the fire department. In others, it is a part of the police department or is an independent public or private safety service. In some areas, a contractor may provide BLS or ALS service, whereas in other areas, a hospital-based program, possibly covering several towns, may provide the ambulance services.

New technologies are constantly being developed that can assist responders in locating their patients. As previously described, cellular telephones can be linked to GPS units to display their location. Responding units can transmit their

position to dispatch, and dispatch can transmit the location of a call to a moving digital map in the unit, complete with turn-by-turn directions. Medical databases can be queried and patient information can be directly downloaded to your computer or uploaded from your laptop to the database. The pace of technological developments in communications makes the latest device soon obsolete, so constant training and education are required to keep your knowledge up-to-date.

Being active in your community will keep you abreast of the best local resources. When you are developing a potential care plan, ask yourself, “Does the receiving facility have the resources needed for this patient?” When you are active in your community, you will know the answer. If the answer is no, the next question, “Is there an appropriate facility within a reasonable distance?” will also be a part of your community knowledge. And of course, remember, your patients have the ultimate decision regarding where they go, as long as they are in stable condition, alert, and oriented.

Clinical Care

As an AEMT, you will use a wide range of emergency equipment. During the AEMT course, you will learn how to use a variety of the appliances and devices that you may need to use on a call. Clinical care describes the various pieces of equipment and scope of practice for using that equipment. You will learn when the use of the equipment or practice is indicated and when it is contraindicated because it will not be of benefit or may cause harm. Although the use of different models and brands of a given device will follow the same generic principles and methods, some variations and peculiarities exist from one model to another. When you join a service, check each key piece of equipment before going on duty to ensure it is in its assigned place, it

works properly, and you are familiar with the specific model carried on your ambulance.

Each AEMT may be called on to drive the ambulance. Therefore, you must familiarize yourself with the roads in your **primary service area (PSA)** or sector. The PSA is the main area in which an EMS agency operates. Before you go on duty, check all the medical equipment and supplies and the communications equipment that the ambulance carries, and ensure that the ambulance is fully fueled, that it has sufficient oil and other key fluids, and that the tires are in good condition and inflated properly. You should test each of the driver's controls and each built-in unit and control in the patient compartment. If you have not driven the specific ambulance before, it is a good idea to take it out and become familiar with it before you respond to a call. Maintenance and safe driving of the ambulance are discussed in detail in Chapter 39, *Transport Operations*.

Human Resources

This component of EMS examines the profession. Human resources deals with the people within EMS systems. Who delivers the care? How are these people compensated for their time and energy? How do other members of the medical community interact and participate within the EMS world? These are some of the questions discussed within the component of human resources. The overarching concept is to encourage the creation of EMS systems that provide an environment where talented people want to work and can turn their passion into a rewarding career.

EMS Agenda 2050 encourages the creation of systems that help to protect the well-being of EMS providers. It also encourages systems to develop career ladders, allowing talented EMS providers ways to use their talent for many years.

Several objectives need to be accomplished to help make a career in EMS a lasting one. As discussed, efforts are being made to ensure EMS providers can relocate from one state to another more seamlessly. From a global point of view, one of the core functions of a state is to provide for and protect its citizens. This obligation has led to the creation of EMS levels that are unique to a specific state. Though effective for any one state, these idiosyncratic EMS levels complicate movement from

Words of Wisdom

An *indication* is a reason for performing an action or giving a medication. A *contraindication* is a reason not to. For example, a fall is an indication for cervical spine immobilization, and hypersensitivity to a medication is a contraindication to giving that medication.

one state to another. One of the functions of the National EMS Scope of Practice Model is to create stable foundations on which each level of EMS provider is grounded. The net effect is to encourage a more consistent definition of “what is an EMT” so providers can serve more freely throughout the United States.

National Registry certification often facilitates licensure in other states. The Interstate Commission for EMS Personnel Practice aims to increase the ability of EMS providers to practice in other states through the Recognition of EMS Personnel Licensure Interstate CompAct (REPLICA). REPLICA is not a form of EMS licensure reciprocity. It simply extends a privilege for EMS personnel from member states to practice on a short-term or intermittent basis under approved circumstances in other member states.

Medical Direction and Control

Each EMS system has a physician **medical director** who authorizes the providers in the service to provide medical care in the field. The appropriate care for each injury, condition, or illness that you will encounter in the field is determined by the medical director and is described in a set of written standing orders and protocols. Protocols are described in a comprehensive guide delineating the scope of practice for AEMTs. Standing orders are part of protocols and designate what an AEMT is required to do for a specific complaint or condition. Providers are not required to consult medical control before implementing standing orders.

The medical director is the ongoing working liaison among the medical community, hospitals, and the AEMTs in the service. If treatment problems arise or different procedures should be considered, these are referred to the medical director for decision and action. To ensure that proper training standards are met, the medical director determines and approves the continuing education and training that are required of each AEMT in the service and approves any obtained elsewhere.

Medical control is off-line (indirect) or online (direct), as authorized by the medical director. Online medical control consists of direction given over the phone or radio directly from the medical director or designated physician. The medical direction can be communicated by the physician's designee;

FIGURE 1-4 Online or direct medical control is provided by a physician.

© dusanpetkovic/iStock/Getty Images Plus/Getty Images.

it does not have to be communicated personally by the physician. Off-line medical control consists of standing orders, training, and supervision authorized by the medical director. You must know and follow the protocols developed by your medical director.

The service's protocols will identify an EMS physician who can be reached by radio or telephone for medical control during a call (**FIGURE 1-4**). This is a type of direct online medical control. On some calls, once the squad has initiated any immediate urgent care and given its radio report, the online medical control physician may confirm or modify the proposed treatment plan or may prescribe additional special orders that you are to follow for that patient. The point at which you should give your radio report or obtain online medical direction will vary based on the patient's condition. For example, once the patient has been assessed and you believe that the patient needs a treatment that requires medical control's permission, you would contact medical control.

Legislation and Regulation

Although each EMS system, medical director, and training program has vast latitude, their training, protocols, and practices must conform to the EMS legislation, rules, regulations, and guidelines adopted by each state. Medical directors, along with EMS supervisors and others, develop protocols for individual service areas based on the training levels of the EMS providers in that area. The state

EMS office is responsible for authorizing, auditing, and regulating all EMS systems, training institutions, courses, instructors, and providers within the state. In most states, the state EMS office obtains input from an advisory committee made up of representatives of the services, service medical directors, medical associations, hospitals, training programs, instructors' associations, EMT associations, and the public in that state.

EMS is usually administered by a senior EMS official. Daily operational and overall direction of the service is provided by an appointed chief executive officer and several other officers who serve under this person. When the EMS unit is a part of a fire or police department, the department chief will usually delegate the responsibility for directing EMS to an assistant chief or other officer whose sole responsibility is to manage the EMS activities of the department. To provide clear guidelines, most services have written standard operating procedures and policies. When you join a service, you will be expected to learn and follow its protocols.

The chief executive of the service is in charge of the necessary administrative tasks (such as scheduling, personnel, budgets, purchasing, and vehicle maintenance) and the daily operations of the ambulances and crews. Except for medical matters, this person operates as the chief (similar to a fire chief or police chief) of EMS for the service and the PSA that it covers.

Integration of Health Services

EMS does not work in a vacuum. EMS personnel travel to people's homes and to incident locations. Once on scene, they deliver care and transport the patient to a care facility. Integration of health

services means the prehospital care you administer is coordinated with the care administered at the hospital. When you deliver a patient to the ED, you are simply transferring that patient to another care provider. The excellent care that you began should be continued in the ED. This component helps to decrease errors, to increase efficiencies, and, most of all, to ensure the patient receives comprehensive continuity of care.

Words of Wisdom

Accurate, comprehensive documentation is a must for the integration of health services to work effectively. Each component of the system must know what care the previous component provided (eg, medications given) to offer optimal care for the patient. Failure to document a medication that was provided could result in a repeat dosage by the next provider, resulting in an overdose to the patient.

Some EMS systems have collaborated with local hospitals to improve patient outcomes associated with time-sensitive treatment like heart attacks, trauma, and stroke. This is accomplished through special training in the EMS system and certain hospital departments. For example, when paramedics determine a patient is having a heart attack, they alert the ED. The personnel in the ED notify the cardiac catheterization team, or you may be directed to transport the patient to a cardiac specialty center. As a result, the key personnel are ready to begin critical treatments as soon as the patient arrives at the hospital. Similar activities take place for stroke and trauma patients.

YOU are the Provider

Part 3

Midway through your first day of orientation, you are introduced to the medical director. He explains to you his roles and responsibilities as medical director of the service. He further tells you specific rules and regulations that you, as an AEMT, must follow on every call to maintain your certification.

5. What dictates the skills that you, as an AEMT, may perform in the course of your duties?
6. What are the two types of medical control?

Mobile Integrated Healthcare and Community Paramedicine

Mobile Integrated Healthcare (MIH) is a system of delivering health care that utilizes the prehospital spectrum. It has evolved as a result of the Patient Protection and Affordable Care Act (more commonly known as the Affordable Care Act), with the goal to facilitate improved access to health care at an affordable price. In the MIH model, health care is provided within the community, rather than at a physician's office or hospital. An integrated team of health care professionals, including EMS providers, delivers health care services in the community and connects patients with other valuable resources such as social services. An advantage of this model is that it offers access to care to patients who live in communities with limited medical resources and leads to better service for those who are homebound or disabled.

This new branch of health care is causing the evolution of additional training levels for EMS providers. One training aspect is **community paramedicine**, in which experienced paramedics receive advanced training to equip them to provide services within a community. In addition to the patient care services a paramedic would typically provide, services provided by community paramedics may include performing health evaluations, monitoring chronic illnesses or conditions, obtaining laboratory samples, administering immunizations, and serving as a patient advocate.

Street Smarts

Community paramedicine and MIH teams may be the best example of the team concept of continuum of care. In the MIH model, health care is provided within the community rather than at a physician's office or hospital. The success of MIH programs have shown that EMS providers, working as a unified team with in-hospital and other community health care providers, can improve patient outcomes, increase patient satisfaction, and reduce health care costs.

Evaluating Quality and Safety

The medical director is responsible for maintaining **quality control** to ensure all staff members who are involved in caring for patients meet appropriate

medical care standards on each call. To provide the necessary quality control, the medical director and other involved staff review patient care reports (PCRs), audit administrative records, and survey patients.

Continuous quality improvement (CQI), which may also be known as quality assurance (QA), is a dynamic, circular system of continuous internal and external reviews and audits of all aspects of an EMS call. To provide CQI, periodic run review meetings are held in which all staff involved in patient care review the run reports and discuss any areas of care that seem to need change or improvement. Positive feedback is also discussed. If a problem seems to be repeated by a specific AEMT or crew, the medical director will discuss the details with the providers involved and, if necessary, assign remedial training or some other educational activity. The medical director also ensures the appropriate continuing education and training are available.

Information and skills in emergency medical care change constantly. You will need refresher training or continuing education as new modalities of care, equipment, and understanding of critical illnesses and trauma develop. In addition, when you have not performed a particular procedure for some time, skill decay may occur. Therefore, your medical director might establish a CQI process to correct the deficit. For example, an ED physician noted that despite their assessments, many AEMTs were missing a high number of closed long bone fractures, resulting in inadequate prehospital care. A subsequent audit of calls led to a review and retraining session for assessment and care of fractures. This same process can apply to CPR or any other type of skill that you do not use often. You may also choose to follow up on specific patients delivered to the hospital. By doing so, you have the opportunity to critique your prehospital care and, in turn, improve any weak areas. As an AEMT, you have an ongoing commitment to ensure your skills and knowledge are current.

Another function of the evaluation process is to determine ways to limit or eliminate human error and improve patient safety. During the delivery of EMS, as with any occupation, there are times when errors can occur. Communicating with other AEMTs or transferring the patient to the ED presents circumstances where errors can happen. Driving to the scene can be hazardous. A patient can be dropped during lifting and moving. Remember,

errors can occur at any point during the call that can result in harm to the patient, public, and you.

It is important that you strive to eliminate errors as much as possible. Understanding the circumstances of the errors helps to minimize them. There are three main sources of errors. Errors can occur as a result of a *rules-based failure*, a *knowledge-based failure*, or a *skills-based failure* (or any combination of these). For example, does an AEMT have the legal right to administer the particular medication needed by the patient? If not, a rules-based failure has occurred if an AEMT assists with the administration. Does an AEMT know all pertinent information about the medication being administered? If not, a breakdown at this point, such as the administration of the wrong medication, would be referred to as a knowledge-based failure. Finally, is the equipment operating and being used properly? If not, a skills-based error has occurred. Any error can come from multiple sources.

Agencies need to have clear protocols, which are detailed plans that describe how certain patient issues, such as chest pain or shortness of breath, are to be managed. These protocols need to be understood by all AEMTs within the service. Limiting errors requires the efforts of both the EMS agency and EMS personnel.

The environment can also contribute to errors. Are there ways to limit distractions and minimize interruptions? Can you find what you need in a timely manner? Sometimes the solution is as easy as ensuring flashlights are available on all ambulances or ensuring all medications and equipment are properly labeled and organized.

When you are about to perform a skill, ask yourself, “Why am I doing this?” Consider the reason for your actions, and allow yourself time to reflect and make an informed decision. If you have considered what to do and cannot come up with a solution, ask for help. Talk with your partner, contact medical control, or call your EMS supervisor.

Another way to help limit medical errors is to use checklists, reference material, and “cheat sheets.” Have a copy of your protocol book with you. Emergency physicians have many reference materials available to them. Physicians recognize they cannot memorize everything, so referencing a book or a reliable Internet resource helps ensure the use of accurate information. Apps are also available for reference.

Use downtime to refresh the skills used less often. Use decision-making aids, such as algorithms, and reflect on what has been done as an informal critique for future improvement of performance. Finally, after a troublesome call, sit down and talk. Talk with your partner and/or your supervisor. Discussing the events that just happened provides an excellent avenue for learning. Your discussions can help lead to changes in protocol, how equipment is stocked, or even the purchase of new equipment.

Street Smarts

Short routine debriefings with your partner after each run can identify problems before they build up. Questions to consider might include the following:

- What did we do?
- Were there any equipment problems?
- What went well?
- What could have gone better?

Information Systems

EMS is not dissimilar to any other profession in today's world. Without computers, the job would be much more difficult. An information system allows EMS providers to efficiently document the emergency medical care that has been delivered. Once that information is stored electronically, it can be used to improve care. For example, how many times has a department seen patients with chest pain? What is the average on-scene time for major trauma patients? How many AED runs has the department had? These questions and many more can be answered using the information gathered from computerized medical records.

This information is used for a variety of purposes. It is used to construct educational sessions for the department. Data from ambulance activity logs are used to justify hiring more personnel. Examining the types of patients and their frequency can provide the foundation for the purchase of new equipment and guide continuing education sessions. This information can also be combined with other database resources, such as from a hospital, to determine patient outcome. Departments from around the United States are sending information

to Washington, DC, so a national snapshot of EMS activities can be obtained. Information gathered by NEMSIS can be found at www.nemsis.org.⁵ This information will be used to better plan for the needs of EMS systems today and in the future.

System Finance

All EMS departments need a funding system that allows them to continue to provide care; however, the type of system needed depends on many variables. There are several types of EMS departments in the United States. The *Journal of Emergency Medical Services* reports annually on how EMS is delivered in the 200 largest cities within the United States. The 2013 survey included more participation from the 15 largest cities, so the results may vary from previous years. **TABLE 1-4** provides the breakdown of types of EMS services within the United States for the year 2013.

These departments may have paid or volunteer personnel, or a mix of both. Financial resources are available for EMS departments through taxation, fee for service, paid subscription, donations, federal/state/local grants, fund-raisers, or combinations of same. Which financial system is used depends on the needs and makeup of each EMS department.

How are AEMTs involved with the financial side of EMS? You may be asked to gather insurance information from patients, secure signatures on certain documents such as HIPAA (Health Insurance Portability and Accountability Act; discussed later in the chapter) notifications, or obtain written permission from patients to bill their health insurance companies. These steps are important to the health care process. When you do not provide needed

Street Smarts

Proper documentation by the EMS provider can substantially affect an agency's ability to process medical insurance claims, provide eligibility for financial grants for training or equipment, and provide evidence of competent practices.

information, the patient may be billed, rather than the insurance company.

As the health care system in the United States evolves, billing is changing at every level. In 2020, the Centers for Medicare and Medicaid Services (CMS) implemented a pilot program in a small group of EMS agencies, known as Emergency Triage, Treat, and Transport (ET3). Rather than an EMS system getting paid only for transportation to an ED, ET3 strives to reimburse EMS systems for providing the right patient with the right care at the right time. This program allows transport to EDs for patients who need that level of care, but also sets up a payment model for patient transport to alternative destinations, such as urgent care centers or doctors' offices, or on-scene treatment with no transport.

Education Systems

Your training will be conducted by many knowledgeable EMS educators. In most states, the instructors who are responsible for coordinating and teaching the AEMT course and continuing education courses are approved and licensed by the state EMS office or agency. Most EMS training programs must adhere to national standards established by the accrediting organizations CoAEMSP (Committee on Accreditation of Educational Programs for the Emergency Medical Services Professions) and CAA-HEP (Commission on Accreditation of Allied Health Education Programs). To be licensed in some states, an instructor must have extensive emergency medical and educational training and teach for a designated period while being observed and supervised by an experienced instructor. ALS-level instructors and directors must hold a 4-year degree.

Generally, ALS training is provided either in a college/university, adult career center, or hospital setting. In most states, educational programs that provide ALS training must be approved by the state and have their own medical director. In these

TABLE 1-4 Types of EMS Services That Transport Patients in the 200 Largest Cities Within the United States

Organization Type	Percentage of Service Provided
EMS	28.1%
Fire department	44.9%
Hospital/private/volunteer	27.0%

Abbreviation: EMS, emergency medical services

courses, many of the lectures and small group sessions are presented by the medical director or other physicians, nurses, and EMS instructors. In clinical sessions, in which supervised practice is obtained in the ED or other in-hospital settings, students are supervised directly by physicians and nurses.

The quality of care you provide depends on your ability and the quality of your training. Therefore, your instructor and the many others who develop and participate in your training program are key members of the emergency care team.

When you no longer have the structured learning environment that is provided in your initial training course, you must assume responsibility for directing your own study and learning. As an AEMT, you are required to attend a certain number of hours of continuing education approved for AEMTs each year to maintain, update, and expand your knowledge and skills. In many services, the required hours are provided by the training officer and medical director. In addition, most EMS education programs and hospitals offer a number of regular continuing education opportunities in each region. You may also attend state and national EMS conferences to help you stay current about local, state, and national issues affecting EMS. Because there are many levels of licensing, you should ensure the continuing education you receive is approved for AEMTs. Whether you take advantage of these opportunities depends on you. You may decide to remain an AEMT or you may want to achieve a higher level of training and certification, but whatever you choose, the key to being a good AEMT and providing high-quality care is your commitment to continual learning and increasing your knowledge and skills.

AEMTs possess special knowledge and skills that are directed to the care of patients in emergency situations. The authority that is delegated to you to care for patients is a very special one. Maintaining

your knowledge and skills is a substantial responsibility. Knowledge and skills that are learned in any profession weaken when they are not used on a continual basis. Consider the steps involved in CPR, for example. If you have not used these skills since your original training, it is unlikely you will perform CPR proficiently. Frequent continuing education, refresher courses, and computer-based or manikin-based self-education exercises are measures you can take to maintain your skills and knowledge.

Prevention and Public Education

Prevention and public education are often closely associated with each other. They are components of the EMS system where the focus is on public health. **Public health** examines the health needs of entire populations with the goal of preventing health problems and works to prevent illness and injury by being proactive. Significant accomplishments of the public health systems include vaccination programs, helmet and seat belts laws, tobacco use laws, prenatal screenings, and the formation of the Food and Drug Administration.

Health care in the United States is currently in a state of flux. The high-tech, on-demand style of care that is prevalent has two major drawbacks. One, it is very expensive. In the United States, more than 17.14% of the gross domestic product is accounted for by health care.⁶ Two, it may not deliver a better product. The Centers for Disease Control and Prevention (CDC) reports people born in the United States have an average life expectancy of almost 79 years.⁷ There are 35 other countries in which people are living longer.

EMS can work with public health agencies on both primary and secondary prevention strategies. **Primary prevention** focuses on strategies that will

YOU are the Provider

Part 4

The final speaker for your first day of orientation is the service's QA/CQI officer. He explains to you the required format for documenting your calls, as well as what can be expected of him.

7. What is the purpose of a QA/CQI meeting?
8. How can a QA/CQI review make you a better provider?

Words of Wisdom

A good example of public health at work is the common product, salt. The next time you buy salt, look at the contents. In the United States, most salt is sold with the additive iodine. It was discovered years ago that certain thyroid diseases, such as goiter (abnormally large thyroid gland), are caused by a decrease in iodine levels within people's diets. The solution was to add this important element into a commonly used food source. Today, goiter is rare within the United States.

prevent an event from ever happening. For example, in the early 1900s, polio was a devastating disease causing death and disability for thousands of Americans. It was discovered that a vaccine could be developed to prevent the disease. In the span of one generation, the disease was virtually eliminated. Vaccinations are a good example of primary prevention within public health.

In June 2009, the World Health Organization (WHO) declared the swine flu (H1N1) virus to be at pandemic levels, which meant the virus had spread throughout the world. The CDC estimated that between April 2009 and April 2010, there were approximately 60.8 million cases and 12,469 deaths in the United States.⁸ By August 2010, the WHO declared an end to the pandemic. More recently, coronavirus disease 2019 (COVID-19), first identified in China in 2019, rapidly spread as a pandemic, with the first documented case in the United States on January 20, 2020.⁹ EMS providers were forced into many unconventional roles due to the rapid spread of the virus and inadequate number of providers. As vaccination proceeds and expands beyond hospital settings where the first COVID-19 vaccinations occurred, EMS providers may be called on to assist in the administration of the vaccine.

Other examples of primary prevention include ensuring people know the dangers of drinking and driving, and the harmful effects of using tobacco and other drugs. There are several ways you can contribute to primary prevention strategies. Become involved in programs that educate the community. Small actions can lead to big differences.

In a **secondary prevention** strategy, the event has already happened. The question then becomes, how can we decrease the effects of the event?

Helmets and seat belts do not prevent the accident from happening, yet they prevent serious injuries from occurring as a result of the accident. The next time you drive down a major roadway, take note of the construction of the guardrails. There have been significant changes in guardrail construction over the years as more information has become available on what happens during a vehicle collision.

You may also be involved in the surveillance of illnesses and injuries. The PCR that are generated by EMS personnel can be used to determine if a serious, widespread condition exists. For example, EMS is in a perfect position to provide statistical information to the local government about collisions. Injury surveillance data can be used to determine ways to improve a dangerous intersection, to prevent crashes from ever happening, or to limit the severity of injuries to drivers.

As discussed, you can help educate the public. People may not understand why an incident has happened. A parent allows her 15-month-old child to play outside with other children unsupervised. The child falls and cuts her hand. EMS arrives and determines the cause of the injury is obvious. You can work professionally, respectfully, and kindly with the parents to help educate them on how to prevent this injury from occurring in the future.

The public may not understand the education that EMS providers have and what services they can provide. You can go to local schools and teach children to call 9-1-1 when there is a medical emergency. EMS personnel can work with local health care institutions to inform local residents when to call for an ambulance and when other transportation methods are more appropriate. Efforts to use social media to alert the public of a cardiac arrest are also developing. Consider advocating for social-media-directed or mobile phone dispatch systems that encourage laypeople trained in CPR to respond to episodes of cardiac arrest that occur close to them.

Teaching people how to perform CPR, how to help a choking victim, and even how to assist in the delivery of a baby are all aspects of public education. Educating the public on the benefits of compression-only CPR is another example. One of the important effects of public education is an increase in public respect for EMS. When people understand what it means to work on an ambulance and provide care to the sick and injured, they are more likely to consider EMS a vital part of the

Words of Wisdom

Human Trafficking

Human trafficking is a type of modern-day slavery. Through the use of force, fraud, and/or coercion, perpetrators establish control over other human beings and exploit them for profit. The number of victims of human trafficking is unknown due to its underground nature. According to the International Labor Organization, it is estimated that 40.3 million people were victims of modern slavery in 2016 and there is an average of 5.4 victims of human trafficking for every 1,000 people in the world.¹⁰

Trafficking exists in multiple forms, including child and forced labor, child soldiers, and the commercial sexual exploitation of children. Those individuals most at risk of exploitation include individuals from low socioeconomic backgrounds and marginalized communities, immigrants, members of minority cultures (such as the LGBTQ community), children in foster care, individuals who are homeless or have run away from home, individuals with disabilities, and victims of natural disasters. Although members of virtually any demographic group could be included on this list, women and children top the list.

Though some victims are sold into slavery, and others are forcibly kidnapped, the most common scenario involves traffickers who take advantage of an individual's vulnerability, including offers of a better life, romance, or drugs. Physical force is often used in establishing dominance, along with threats of violence against family members or loved ones. Victims are frequently exposed to harsh physical conditions, starvation, health risks, rape, and substance abuse. The severity of the treatment may also lead to various mental health issues, including posttraumatic stress disorder.

Trafficked persons are often reluctant to report or seek help for numerous reasons, including the following:

- They do not recognize the situation they are in.
- They have no idea where or how to seek help.

- They have a bond with their trafficker and thus a sense of obligation to "help" the person.
- They or their families are in debt to the trafficker (often from the purchase of drugs).
- They are fearful of deportation.
- They are addicted to drugs.
- They feel they or their families will be harmed if they seek help.
- They are unfamiliar with their surroundings (especially when held in a country other than their own) and do not know whom to trust.
- They are fearful of law enforcement.
- They are earning much-needed money to send to their families.

Contrary to popular belief, human trafficking often occurs in plain sight. While there are many indicators that a person may be the victim of trafficking, the following is a brief list of signs you may encounter when responding to a routine EMS call:

- The patient shows signs of physical abuse or injury.
- The patient is accompanied everywhere by a person who speaks for the patient or will not allow the patient to speak when addressed directly.
- The patient appears fearful or under the control of another person.
- The patient has ongoing health issues that have not been addressed.
- The patient is unfamiliar with the neighborhood in which the scene is located.
- The patient appears to be traveling with a minimal or inappropriate amount of luggage or belongings.
- The patient has a lack of identification documents or does not have control over personal identification documents.
- The patient is a juvenile engaged in a commercial sex act.

You should report any such red flags to the National Human Trafficking Hotline at 1-888-373-7888. Follow local protocols for further reporting of suspicious situations.

public health care system. This change in attitude can be powerful and lead to increased EMS funding and greater respect for EMS as a profession.

EMS Research

Traditional medical practice is based on medical knowledge, intuition, and judgment. In the early years of EMS, many standards relating to

professionalism, protocols, training, and equipment were developed from EMS providers' direct experience. Now, ongoing EMS research provides a scientific basis for standards, in a way similar to research in any other health care profession.

In the early days of EMS, it was believed major trauma patients needed to be stabilized on the scene before they were transported. Paramedics would start IV lines and use advanced airways.

There was no foundation to support this behavior; it was just assumed that this care needed to be done. After compiling substantial prehospital EMS research, it was determined major trauma patients needed to be transported to an operating room more than they needed IV fluids. This is the power of EMS research.

Virtually all aspects of health care today use **evidence-based medicine (EBM)**. EBM is focused on procedures that have proven useful in improving patient outcomes and on individual patient characteristics and values. Although not every aspect of EMS has enough research to be truly evidence-based, many EMS systems and states now consult the *National Model EMS Clinical Guidelines* from the National Association of State EMS Officials. These treatment guidelines are based on a review of current research and expert consensus. All aspects of the AEMT role are currently being researched, not only within the academic community, but increasingly within the practitioner community, as every AEMT has something to contribute to improving the role.

EMS research may be performed by EMS providers or other people who are studying a particular branch of medicine. AEMTs will be involved in research typically through gathering data. You may be part of a study to determine how much oxygen should be given to patients with shortness of breath. You may be involved in a study to track the time it takes to transport serious trauma patients to the ED. Your job is to ensure all information about patients is recorded carefully. The information gathered is analyzed by others to answer these questions, and the results are shared with the rest of the EMS community to improve patient care practices. Traditional medical practice is based on such research.

Research can also be conducted at each EMS facility. EMS personnel can examine patient care records to determine where the department can improve. This information can be used to generate educational sessions for AEMTs or can be used to plan public education/public prevention strategies. High-quality patient care should focus on procedures useful in improving patient outcomes through sound research. It is important for EMS providers to stay current on the latest advances in health care. In the past, the American Heart Association (AHA), in concert with the International Liaison Committee on Resuscitation (ILCOR), revised the

Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiac Care every 5 years. As of 2015, it was determined a 5-year cycle is insufficient to keep pace with the rapidly evolving research in resuscitation science, so it is planned for the guidelines to be updated on a more regular basis. The ILCOR guidelines are an excellent example of evidence-based medical decision making in progress. These changes occur because more information is known.

One word of caution: When reading new research results, make sure you understand what the results mean. Research information can be powerful, but it is often powerful within a very limited setting. A manufacturer of a defibrillator boasts its new machine will terminate ventricular fibrillation on the first shock 95% of the time. On the basis of this information, you may immediately want to buy this new product. Terminating ventricular fibrillation is certainly a positive result, but does this defibrillator save more lives than other defibrillators? In this example, the manufacturer is reporting that the defibrillator can terminate ventricular fibrillation, not that the defibrillator can save more lives. People who do not examine the research will often make hasty conclusions.

Be skeptical when reading research. Ask questions and conduct your own research. Conclusions that seem too good to be true are usually not true.

Street Smarts

Remember, each patient is unique and has different needs. An algorithm, or treatment plan, should be altered to meet the needs of each individual patient as opposed to using an “across-the-board” approach.

Transport Considerations and Communication

Transport to Specialty Centers

In addition to hospital EDs, many EMS systems include specialty centers that focus on specific types of care (such as trauma, burns, poisoning, or psychiatric conditions) or specific types of patients (for example, children). Specialty centers require in-house staffs of surgeons and other specialists; other facilities must page operating teams, surgeons, or other specialists from outside the hospital. Typically, only a few hospitals in a region are designated as specialty centers. Transport time to a specialty center

may be slightly longer than the time to an ED, but patients will receive definitive care more quickly at a specialty center. You must know the location of the centers in your area and when, according to your protocol, you must transport the patient directly to one. Sometimes, air medical transport will be necessary. Local, regional, and state protocols will guide your decision in these instances.

Interfacility Transports

Many EMS systems provide interfacility transportation for nonambulatory patients or patients with acute and chronic medical conditions requiring medical monitoring (**FIGURE 1-5**). This transportation may include transferring patients to and from hospitals, skilled nursing facilities, board and care homes, or even their own residence.

During ambulance transportation, the health and well-being of the patient is the responsibility of AEMTs. You should obtain the patient's medical history, chief complaint, and latest vital signs and provide ongoing patient assessment. In certain circumstances, depending on local protocols, a nurse, physician, respiratory therapist, or medical team will accompany the patient, especially when the patient requires care that extends beyond the scope of practice of AEMTs.

Working With Hospital Staff

You should become familiar with the hospital by observing hospital equipment and how it is used, the functions of staff members, and the policies and procedures in all emergency areas of the hospital. You will also learn about advances in emergency

medical care and how to interact with hospital personnel. This experience helps you understand how your care influences a patient's recovery and will emphasize the importance and benefits of proper prehospital care. It will also show you the consequences of delayed care, inadequate care, or poor judgment.

Physicians are not likely to be in the field with you to provide personal, on-the-spot instructions. However, you may consult with appropriate medical staff by using the radio through established medical control procedures.

A physician or nurse may serve as an instructor for medical subjects in your training program. Through these experiences, you will become more comfortable using medical terms, interpreting patient signs and symptoms, and developing patient management skills. The best patient care occurs when all emergency care providers have close rapport. This rapport allows you and hospital staff the opportunity to discuss mutual problems and to benefit from each other's experiences.

Working With Public Safety Agencies

Some public safety workers have EMS training. As an AEMT, you must become familiar with all the roles and responsibilities of these workers. Personnel from certain agencies are better prepared than you are to perform certain functions. For example, employees of a utility company are better equipped to control downed power lines. Law enforcement personnel are better able to handle violent scenes and traffic control. Recognize that each person has special training and a job to do at the scene. Remember, the best, most efficient patient care is achieved through cooperation among agencies.

Roles and Responsibilities of AEMTs

You will be one of the first health care professionals to assess and treat the patient; as such, you have certain roles and responsibilities (**TABLE 1-5**). Often, patient outcomes are determined by the care that you provide in the field and your identification of patients who need prompt transport. You are responsible for all aspects of EMS, from the preparation of the equipment, to the delivery of care, to providing a good example for others within the community.

FIGURE 1-5 As an AEMT, part of your job may be transporting patients from one facility to another.

© NurPhoto/Contributor/NurPhoto/Getty Images.

TABLE 1-5 Roles and Responsibilities of AEMTs

- Keep vehicles and equipment ready for an emergency.
- Ensure the safety of yourself, your partner, the patient, and bystanders.
- Properly and safely operate the emergency vehicle.
- Be an on-scene leader.
- Perform an evaluation of the scene.
- Call for additional resources as needed.
- Gain patient access.
- Perform a patient assessment.
- Give emergency medical care to the patient.
- Properly and safely move patients.
- Communicate effectively with the patient and advise the patient of any procedures you will perform.
- Give emotional support to the patient, the patient's family, and other responders.
- Maintain continuity of care by working with other health care professionals.
- Resolve emergency incidents.
- Uphold medical and legal standards.
- Ensure and protect patient privacy.
- Give administrative support.
- Constantly continue your professional development.
- Cultivate and sustain community relations.
- Give back to the profession.

© Jones & Bartlett Learning.

Professional Attributes

As an AEMT, you are expected to have certain professional attributes (**TABLE 1-6**). Whether you are paid or a volunteer, you are a health care professional. A professional is skilled and trained for work by extended study or practice. Part of your responsibility is to ensure patient care is given a high priority without endangering your own safety or the safety of others. Another part of your responsibility to yourself, other emergency care providers, the patient, and other health care professionals is to maintain a professional appearance and manner at all times (**FIGURE 1-6**).

Appearance, including uniforms, hair length, and tattoos, is usually regulated by the policies of your department. Your attitude and behavior must reflect your knowledge, proficiency, and sincere dedication to serving anyone who is injured or experiencing an acute medical emergency. A professional appearance and manner help to build

TABLE 1-6 Professional Attributes of AEMTs

Attribute	Description
Integrity	Consistent actions, adheres firmly to a code of honest behavior
Empathy	Shows awareness and consideration about the needs of others
Self-motivation	Discovers problems and solves them without direction
Appearance and hygiene	Uses persona to project a sense of trust, professionalism, knowledge, and compassion
Self-confidence	Knows what you know and what you do not know; asks for help when needed
Time management	Performs or delegates multiple tasks while ensuring efficiency and safety
Communication	Understands others and ensures they understand you
Teamwork and diplomacy	Works with others; knows your place within a team; communicates while giving respect to the listener
Respect	Places others in high regard or importance; understands others are more important than you
Patient advocacy	Constantly keeps the needs of the patient at the center of care; supports patients' rights
Careful delivery of care	Pays attention to detail; ensures what is being done for the patient is done as safely as possible

© Jones & Bartlett Learning.

Street Smarts

It is imperative that you treat all patients with respect and compassion. This extends to concerned relatives on scene as well. Taking a few moments to reassure a distraught spouse or anxious parent goes a long way and requires little effort on your part.

confidence and ease the patient's anxiety. You will be expected to perform under pressure with composure and self-confidence. Patients and families

FIGURE 1-6 A professional appearance and manner help to build confidence and ease patient anxiety.

© Jones & Bartlett Learning.

who are under stress need to be treated with understanding, respect, and compassion.

Most patients will treat you with respect and appreciation, but some will not. Some patients are uncooperative, demanding, unpleasant, ungrateful, and verbally abusive. You must be non-judgmental and overcome your instincts to react poorly to such behavior. Remember, when people are hurt, ill, under stress, frightened, despondent, under the influence of alcohol or drugs, or if they feel threatened, they will often react with inappropriate behavior, even toward the people who are trying to help and care for them. All patients, regardless of their attitudes or beliefs, are entitled to compassion, respect, and the best care that you can provide; this includes patients with special needs, alternative lifestyles, and culturally diverse backgrounds. Personal prejudices or biases should not interfere with appropriate medical care.

Many people in the United States can obtain proper routine medical care when they are ill and are surrounded by relatives and friends who will

help to take care of them. However, when you are called to a home for a medical problem that is clearly not an emergency, remember, for some people, calling an ambulance and being transported to the ED is their only way to obtain medical care. You may find yourself in the role of patient advocate in these cases. The issue may arise from lack of funds, special needs, or other problems. If there is an issue that is not addressed, your job as a professional is to bring it to the attention of the professionals who are designated to find assistance for patients in need. It may be as simple as providing transportation or as complex as investigating a possible abuse or neglect case.

Street Smarts

Studies have shown that when the provider pays attention to detail, patients are more likely to feel that the provider cares for them as individuals.

As a new AEMT, you will be given a lot of advice and training from the more experienced providers with whom you serve. Some may voice a callous disregard for some patients. You should not be influenced by this unprofessional attitude, regardless of how experienced or skilled they appear.

As a health care professional and an extension of physician care, you are bound by patient confidentiality. Do not discuss your findings or any disclosures made by the patient with anyone but other providers who are treating the patient or, as required by law, the police or other social agencies. If you must discuss a call with other providers, you should be careful to avoid any information that might disclose the name or identity of patients you have treated. Do not gossip about calls and patients with others, even in your own home. The protection of patient privacy has drawn national attention with the passage of the **Health Insurance Portability and Accountability Act (HIPAA)**, which was enacted in 1996 to limit the availability of patients' health care information and penalize violations of patient privacy. You should be familiar with the requirements of this legislation, especially as it applies to your particular practice. For more information on the HIPAA, see Chapter 3, *Medical, Legal, and Ethical Issues*.

YOU are the Provider SUMMARY

1. What is emergency medical services (EMS)?

EMS consists of a team of health care professionals who are responsible for and provide prehospital emergency care and transportation for sick and injured people. Each EMS agency is part of a local or regional EMS system that provides the prehospital components required to deliver proper emergency medical care.

2. Why was the National Registry of Emergency Medical Technicians (NREMT) established?

The NREMT was established to certify and register EMS professionals through a valid and uniform process that assesses their knowledge and skills to ensure competent practice. The NREMT requires a reregistration process every 2 years to ensure continued competence.

3. What is the National EMS Scope of Practice Model?

At the federal level, NHTSA brought in experts from around the country to create the National EMS Scope of Practice Model. This document provides overarching guidelines for the minimum skills each level of EMS provider should be able to accomplish. Because licensure is a state function, at the state level laws are enacted to regulate how EMS providers will operate and are then executed by the state-level EMS administrative offices that control licensure. Finally, the local medical director decides the day-to-day limits of EMS personnel. For example, the medications that will be carried on an ambulance or where patients are transported are both day-to-day operational concerns in which the medical director will have direct input.

The national guidelines are intended to create more consistent delivery of EMS across the country. The only way a medical director can allow an AEMT to perform a skill is if the state has already approved performance of that skill. The medical director can limit the scope of practice but cannot expand it beyond state law. Expanding the scope of practice requires state approval.

4. How does the EMD system work?

Emergency medical dispatch was developed to assist dispatchers in providing callers with vital instructions to help them deal with an emergency until the arrival of EMS crews. Dispatchers are trained and provided with scripts to help them relay relevant instructions to the callers. The system helps the dispatchers select appropriately resourced units to respond to a request for assistance. It is the dispatcher's duty to relay all relevant and available

information to the responding crews in a timely manner. Keep in mind, however, that current technology does not allow the dispatcher to see what is actually going on at the scene and that it is not uncommon for you to find the reality of the call quite different from the dispatch information. A dispatcher can only relay the information provided by the caller.

5. What dictates the skills that you, as an AEMT, may perform in the course of your duties?

Each EMS system has a physician medical director who authorizes the providers in the service to provide emergency medical care in the field. The appropriate care for each injury, condition, or illness that you will encounter in the field is determined by the medical director and is described in a set of written standing orders and protocols. Protocols are described in a comprehensive guide delineating the scope of practice of AEMTs. Standing orders are part of protocols and designate what AEMTs are required to do for a specific complaint or condition.

6. What are the two types of medical control?

Medical control is off-line (indirect) or online (direct), as authorized by the medical director. Online medical control consists of direction given over the phone or radio directly from the medical director or designated physician. Off-line medical control consists of standing orders, training, and supervision authorized by the medical director.

7. What is the purpose of a QA/CQI meeting?

A QA/CQI meeting is part of a circular system of continuous internal and external reviews and audits of all aspects of an EMS call. Periodic run review meetings are held in which all involved in patient care review the run reports and discuss any areas of care that seem to need change or improvement.

8. How can a QA/CQI review make you a better provider?

A QA/CQI review can identify overall problems within a service or EMS system and individual or team performance problems. The review helps to identify the source of the problem and possible solutions. The potential solutions can be evaluated by discussing their potential benefits and risks and by trying the most likely beneficial solutions in a safe setting, such as role playing, and/or in practice, depending on the nature of the problem and solution. You can learn about how to clearly identify problems and to propose and evaluate solutions by participating in QA/CQI meetings. You can also learn new information and techniques by participating in the meetings and by receiving feedback from the meetings.

Prep Kit

Ready for Review

- EMS is the system that provides the emergency medical care needed by people who have been injured or have an acute medical emergency.
- The standards for prehospital emergency care and the people who provide it are governed by the laws in each state and are typically regulated by a state office of EMS.
- The AEMT course you are now taking provides the information and skills you need to pass the examination required to become a licensed AEMT.
- The EMS ambulance is staffed by providers who have been trained to the EMT, AEMT, or paramedic level according to recommended national standards and have been licensed by the state.
- An EMT has training in basic emergency medical care skills, including automated external defibrillation, use of airway adjuncts, and assisting patients with certain medications.
- An AEMT has training in specific aspects of ALS, such as intravenous therapy and the administration of certain emergency medications.
- A paramedic has extensive training in advanced life support, including endotracheal intubation, emergency pharmacology, cardiac monitoring, and other advanced assessment and treatment skills.
- Key components of an AEMT's job include scene size-up, patient assessment, treatment, and packaging. After assessing the scene and the patient, you will provide the emergency care and transport that is indicated by your findings and ordered by your medical director in the service's standing order protocols or the physician who is providing online medical direction.
- The National EMS Scope of Practice Model provides overarching guidelines for the minimum skills each level of EMS provider should be able to accomplish.
- The *EMS Agenda for the Future* is a multidisciplinary, national review outlining the aspects of EMS delivery. There are 14 EMS attributes described in this document.
- When the dispatcher at the 9-1-1 emergency communications center receives a call for emergency medical care, this person dispatches to the scene the designated EMS ambulance squad and any fire, rescue, or police units that may be needed.
- As an AEMT, you will work in a primary service area and be responsible for ensuring all equipment and supplies are functional and ready for use.
- Each EMS system has a physician medical director who authorizes the providers in the service to provide emergency medical care in the field. Medical control is off-line (indirect) or online (direct).
- In the MIH model, health care is provided within the community, rather than at a physician's office or hospital.
- Community paramedicine allows experienced paramedics to receive advanced training to equip them to provide services within a community.
- CQI is a circular system of continuous internal and external reviews and audits of all aspects of an EMS call.
- It is important to determine ways to reduce human error by ensuring you understand your protocols, ensuring your environment is organized and functional, and acting as a patient advocate.
- EMS research and evidence-based decision making are beginning to have a role in functioning as an EMS provider. Stay aware of research, and focus patient care on procedures that have proven effective in improving patient outcomes.
- EMS systems should implement prevention and public education efforts to help reduce the

incidence of illness and injury in communities and to prepare members of the public to respond to common emergencies. These efforts also can raise community awareness of problems such as human trafficking.

- As an AEMT, you will work with many other professionals, including hospital staff and public safety personnel. Remember, the best, most efficient patient care is achieved through cooperation among agencies.

- AEMT attributes include compassion and motivation to reduce suffering, pain, and death in patients who are injured or acutely ill; a desire to provide each patient with the best possible care; commitment to obtain the knowledge and skills that this requires; and the drive to continually increase your knowledge, skills, and ability.
- As a health care professional and an extension of physician care, you are bound by patient confidentiality.

Vital Vocabulary

advanced emergency medical technician (AEMT)

An individual trained in specific aspects of advanced life support, such as intravenous therapy and administration of certain emergency medications.

advanced life support (ALS) Advanced life-saving procedures used to treat medical conditions, such as cardiac monitoring, administration of intravenous fluids and medications, and the use of advanced airway adjuncts. EMTs and AEMTs may be trained in some of these areas.

Americans With Disabilities Act (ADA) Comprehensive legislation that is designed to protect people with disabilities against discrimination.

automated external defibrillator (AED) A device that detects treatable life-threatening cardiac dysrhythmias (ventricular fibrillation and ventricular tachycardia) and delivers the appropriate electrical shock to the patient.

basic life support (BLS) Noninvasive emergency life-saving care used to treat medical conditions, including airway obstruction, respiratory arrest, and cardiac arrest.

certification A process in which a person, an institution, or a program is evaluated and recognized as meeting certain predetermined standards to provide safe and ethical patient care.

community paramedicine A health care model in which experienced paramedics receive advanced training to allow them to provide additional services in the prehospital environment, such

as health evaluations, monitoring of chronic illnesses or conditions, and patient advocacy.

continuous quality improvement (CQI) A system of internal and external reviews and audits of all aspects of an emergency medical services system.

credentialing An established process to determine the qualifications necessary to be allowed to practice a particular profession, or to function as an organization.

emergency medical dispatch (EMD) A system that assists dispatchers in selecting appropriate units to respond to a particular call for assistance and provides callers with vital instructions until the arrival of emergency medical services crews.

emergency medical responder (EMR) The first trained person, such as a police officer, firefighter, lifeguard, or other rescuer, to arrive at the scene of an emergency to provide initial medical assistance.

emergency medical services (EMS) A multidisciplinary system that represents the combined efforts of several professionals and agencies to provide prehospital emergency care to sick and injured people.

emergency medical technician (EMT) An individual trained in basic emergency medical care skills, including automated external defibrillation, use of a definitive airway adjunct, and assisting patients with certain medications.

evidence-based medicine (EBM) An approach to medicine where decisions are based on well-conducted research, methods that have proven effective in improving patient outcomes, and individual patient characteristics and values; recommendations are classified based on the strength of the scientific evidence; also called science-based medicine.

Health Insurance Portability and Accountability Act (HIPAA) The law enacted in 1996 that provides for criminal sanctions as well as for civil penalties for releasing a patient's protected health information in a way not authorized by the patient.

licensure The process whereby a competent authority, usually the state, allows people to perform a regulated job, trade, or profession.

medical control Physician instructions given directly by radio or cell phone (online/direct) or indirectly by protocol/guidelines (off-line or indirect), as authorized by the medical director of the service program.

medical director The physician who authorizes or delegates to the provider the authority to perform health care in the field.

Mobile Integrated Healthcare (MIH) A system of delivering health care services within the community, rather than at a physician's office or a hospital, with an integrated team of health care professionals.

National EMS Scope of Practice Model A document created by the National Highway Traffic Safety Administration that outlines the skills

performed by various emergency medical services providers.

paramedic An individual extensively trained in advanced life support, including endotracheal intubation, emergency pharmacology, cardiac monitoring, and other advanced assessment and treatment skills.

primary prevention Efforts to prevent an injury or illness from ever occurring.

primary service area (PSA) The designated area in which an emergency medical services agency is responsible for the provision of prehospital emergency care and transportation to the hospital.

public health Discipline that is focused on examining the health needs of entire populations with the goal of preventing health problems.

public safety access point A call center staffed by trained personnel who are responsible for managing requests for police, firefighting, and ambulance services.

quality control The responsibility of the medical director to ensure the appropriate medical care standards are met by providers on each call.

reciprocity The recognition by one state of another state's licensure, allowing a health care professional from another state to practice in the new state.

secondary prevention Efforts to limit the effects of an injury or illness that you cannot completely prevent.

Chapter 2

Workforce Safety and Wellness

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Preparatory

Applies fundamental knowledge of the EMS system, safety/well-being of the AEMT, medical/legal, and ethical issues to the provision of emergency care.

Workforce Safety and Wellness

- Standard safety precautions (pp 37–38)
- Personal protective equipment (pp 39–43)
- Stress management (pp 64–66)
- Dealing with death and dying (p 79)
- Prevention of response-related injuries (pp 52–62)
- Lifting and moving patients (Chapter 6, *Lifting and Moving Patients*)
- Prevention of work-related injuries (pp 37–52)
- Disease transmission (pp 35–37)
- Wellness principles (pp 68–73)

KNOWLEDGE OBJECTIVES

1. Define infectious disease and communicable disease. (pp 34–35)
2. Describe the routes of disease transmission. (pp 35–37)
3. Explain the mode of transmission and the steps to prevent and/or manage an exposure to hepatitis, tuberculosis, and human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS). (pp 44–46)
4. Describe the steps to take for personal protection from airborne and bloodborne pathogens. (pp 36–37)
5. Know the standard precautions that are used in treating patients to prevent infection. (pp 37–39)
6. Explain proper handwashing techniques. (pp 39–40)
7. Explain the proper techniques for putting on and taking off personal protective equipment. (p 39)
8. Describe components of an infection control plan. (pp 44–45)
9. Describe the steps to prevent a potential exposure. (p 46)
10. List the ways immunity to infectious diseases is acquired. (pp 47–48)
11. Explain postexposure management of exposure to patient blood or body fluids, including completing a postexposure report. (pp 49–51)
12. Describe the steps necessary to determine scene safety and to prevent work-related injuries at the scene. (pp 52–53)
13. Describe the various hazards that may be encountered and how to prepare for them. (pp 53–56)

14. Explain how to recognize possibly violent situations and which steps to take to deal with them. (pp 56–58)
15. Describe how to handle behavioral emergencies. (pp 57–58)
16. Describe the protective clothing and gear that is available to protect you. (pp 58–62)
17. Explain the physiologic, physical, and psychological responses to stress. (pp 62–64)
18. Describe posttraumatic stress disorder (PTSD) and steps that can be taken to decrease the likelihood that PTSD will develop, including critical incident stress management. (p 64)
19. Describe components that can contribute to stress, such as burnout and compassion fatigue. (pp 66–67)
20. Explain the importance of peer support in maintaining emotional well-being for yourself and your coworkers. (pp 67–68)
21. Identify the steps that contribute to wellness and their importance in managing stress. (pp 68–73)
22. Discuss workplace issues such as diversity, sexual harassment, and substance abuse. (pp 73–75)
23. Describe issues concerning care of the dying patient, death, and the grieving process of family members. (pp 75–77)
24. Describe reactions to expect from critically ill and injured patients and how you can effectively work with patients exhibiting a range of behaviors. (pp 77–80)

SKILLS OBJECTIVES

1. Demonstrate proper handwashing techniques. (p 40, Skill Drill 2-1)
2. Demonstrate how to properly remove gloves. (p 41, Skill Drill 2-2)
3. Demonstrate the necessary steps to prevent a potential exposure situation. (p 46, Skill Drill 2-3)

Introduction

There is an ancient proverb, “Physician, heal thyself.” As providers of health care, physicians need to look after themselves in all respects so that they can minister to others. Ill physicians are in no position to provide care as they were trained to do. That dictum applies to all health care providers and goes well beyond just physical issues. When caring for critically ill and injured patients, many factors and situations can interfere with the ability of the advanced emergency medical technician (AEMT) to treat the patient.

Your personal health, safety, and well-being are vital to an emergency medical services (EMS) operation. As a part of your training, you will learn how to recognize possible hazards and protect yourself from them. These hazards vary greatly, ranging from personal neglect to environmental and human-created threats to your health and safety. You will also learn about the mental and physical stress that you must cope with as a result of caring for the sick and injured. Death and dying challenge you to deal with the realities of human weaknesses and the emotions of the survivors.

It is important to remain calm so that you can perform effectively when you are confronted with horrifying events, life-threatening illness, or injury. A special kind of self-control is needed to respond efficiently and effectively to the suffering of others. This self-control is developed through the following:

- Proper training
- Ongoing experience in dealing with all types of physical and mental distress
- A dedication to serve humanity

Protection From Infectious Diseases

As an AEMT, you will be called on to treat and transport patients with a variety of communicable or infectious diseases. An **infectious disease** is a medical condition caused by the growth and spread of small, harmful organisms within the body. A **communicable disease** is a disease that can be spread from one person or species to another. This chapter covers protection of the AEMT against such diseases. Chapter 16, *Medical Overview*, covers recognition and care of patients with infectious diseases.

Immunizations, protective techniques, and simple handwashing can dramatically reduce the health care provider's risk of **infection** (the abnormal invasion of a host or host tissues by organisms such as bacteria, viruses, or parasites). When these protective measures are used, the risk of the health care provider contracting a serious communicable disease is negligible. Proper cleaning and disinfecting of the ambulance and equipment will also help to prevent transfer of illnesses to other patients.

Along with personal protection, it is necessary to inform other health care workers who may come in contact with the patient of the potential risk. Discretion is imperative when communicating with other providers. Sensitive patient history should not be given out over the radio during your patient report. However, during your transfer of care, you should provide a complete patient history for the receiving facility. In addition, you should include all patient history in your written documentation.

Routes of Transmission

Many people confuse the terms *infectious* and *contagious*. In fact, all contagious diseases are infectious, but only some infectious diseases are contagious. For example, pneumonia caused by pneumococcal bacteria is an infectious process, but it is not contagious. In other words, the bacteria will not be transmitted from one person to another. However, other infectious agents, such as the **hepatitis B** virus, are contagious because they can be transmitted from one person to another.

A **pathogen** is a microorganism that is capable of causing disease in a host. A **host** is simply the

organism or person invaded by the pathogen. An infectious disease, then, is a disease that is caused by an infection. For example, Lyme disease is an infectious disease caused by the *Borrelia burgdorferi* bacterium, which lives in deer ticks. However, Lyme disease is not contagious. Again, a contagious or communicable disease can be transmitted from one person to another. The only way to get Lyme disease is to be bitten by a deer tick.

Although all infections result from an invasion of body spaces and tissues by germs, different germs use different means of attack. These means are known as the mechanisms of transmission. **Transmission** is the way an infectious disease is spread. Infectious diseases can be transmitted in several ways—contact (direct or indirect), airborne, foodborne, and vector-borne (transmitted through insects or parasitic worms) transmission.

Contact transmission is the movement of an organism from one person to another through physical touch (**FIGURE 2-1**). There are two types of contact transmission: direct and indirect. **Direct contact** occurs when an organism is moved from one person to another through touching without any intermediary.

Words of Wisdom

Routes of Transmission

- Contact (direct or indirect)
- Airborne
- Foodborne
- Vector-borne

YOU are the Provider

Part 1

You and your partner are returning to your station after dropping off a patient at the hospital in a neighboring county when you witness a vehicle in front of you lose control and roll multiple times. You activate your emergency lighting and stop at the scene. As you approach the vehicle, you find one occupant restrained in the driver's seat and note copious amounts of blood. The patient appears to have minor wounds despite the bleeding; he immediately states that he is HIV-positive (human immunodeficiency virus-positive).

1. Do you have a duty to provide care to this patient?
2. What is the minimal amount of personal protective equipment (PPE) you would want to have on prior to exiting the ambulance?
3. What is the minimal amount of PPE you would want to have on prior to initiating care?

FIGURE 2-1 Finger infection resulting from not wearing gloves during patient contact.

© DermQuest.com. Used with permission of Galderma S.A.

The scenario of a vehicle crash can help you understand how transmission occurs through direct contact. Suppose the driver of the vehicle has hepatitis C and is bleeding from an arm injury. The AEMT caring for the patient is not wearing gloves and has a small, unnoticed cut on his hand. As the AEMT handles a bloody dressing, the hepatitis virus moves from the victim's blood on the dressing into the AEMT's body through the cut on the hand, thereby infecting the AEMT. This is an example of direct contact, where blood is the vehicle for transmission of the pathogen. **Bloodborne pathogens** are microorganisms that are present in human blood and can cause disease in humans. Another example of direct contact is sexual transmission. Patients who are infected with the **human immunodeficiency virus (HIV)** can transfer the virus to their partners during sex.

Indirect contact involves the spread of infection between the patient with an infection to another person through an inanimate object. The object that transmits the infection is called a fomite. Suppose that, when caring for the same patient from the previous example, the AEMT wore gloves. As the AEMT was caring for the patient, blood got onto the ambulance stretcher. If the stretcher is not correctly cleaned afterward, the virus might remain on the stretcher and be transmitted to someone else days later. Needlesticks are another example of the spread of infection through indirect contact. In this case, the virus moves from the patient to the needle to the health care provider. This route of transmission was common many years ago before the advent of safety equipment such as needleless intravenous (IV) systems.

Airborne transmission involves spreading an infectious agent through mechanisms such as droplets or dust. The common cold, for example, moves from person to person by coughing and sneezing. Interestingly, when a person sneezes, the moisture from the airway moves forcefully and quickly through a narrow opening. If the moisture droplets are large, they travel short distances and can be involved in direct contact transmission. If the droplets are very small, they are turned into an aerosol and can float in the air for long distances. Sneezing can actually transmit disease through both direct contact and airborne routes.

Because of airborne transmission, it is unsanitary to use your hands to cover a cough or sneeze because the organism travels onto your hands. If you then touch a telephone, doorknob, or a patient, the organisms will travel to that point as well. Using a tissue when coughing or sneezing is better for controlling the spread of organisms, but you then have a piece of paper full of organisms. If wearing sleeves, the best technique to avoid contaminating your hands is to cough or sneeze into your arm/sleeve. Because you do not touch objects with your inner arms, the risk of moving the organism to an object or person is reduced (**FIGURE 2-2**). The organisms are trapped in the fabric and will eventually die.

Foodborne transmission involves the contamination of food or water with an organism that can cause disease. When food is prepared, it is

Words of Wisdom

For some cases in which standard N95 masks are not available or long periods of care for a highly infectious patient are needed, a powered air-purifying respirator (PAPR) may be used. A PAPR provides positive airflow into a loose-fitting hood or tight-fitting facepiece through a filter or cartridge powered by a battery. Although these devices are often more comfortable to work in than the standard goggles and masks, they are expensive, take considerable room to store, and require special training. PAPRs may also limit the AEMT's ability to have a full field of vision and to hear using a stethoscope. Thus, the PAPR is typically deployed only to special response teams in EMS systems rather than being readily available on every ambulance.

FIGURE 2-2 Coughing/sneezing techniques. **A.** Poor coughing/sneezing technique. **B.** Acceptable coughing/sneezing technique. **C.** Best coughing/sneezing technique.

A: © Denis Pepin/Shutterstock; B: © Zsolt Biczó/Dreamstime.com; C: © Seabarnes/Dreamstime.com.

important to ensure that raw meats do not come in contact with other foods to prevent the spread of bacteria. It is also important that food is prepared and stored properly at all times to minimize the possibility of illness. Proper cleaning of food preparation surfaces, as well as good handwashing techniques, before and after use also helps to decrease the likelihood of transmitting foodborne bacteria.

Transmission of some illnesses occurs via the fecal–oral route, when there is ingestion of food or water that has been contaminated by infected feces. One example of contamination is the use of human waste as fertilizer.

Vector-borne transmission involves the spread of infection by animals or insects that carry an organism from one person or place to another. In the Middle Ages, the Black Death (bubonic plague) is estimated to have killed as much as half the population in Europe. This disease is thought to have been transmitted by a flea that lived on rats. The vector (the fleas) was unaffected by disease, and neither were the rats (the hosts). As the rats moved, so did their fleas. When the fleas bit humans, they infected them with the disease, which proved deadly to the humans. Lyme disease is spread in much the same way, with ticks (vectors) being carried on deer (unaffected hosts) and then biting humans to transmit the pathogen. In the vector-borne disease of rabies, however, the vector (raccoon, skunk, or other species) may also develop the disease; it transmits the rabies virus to humans through its saliva (biting or drooling).

Safety

Other potentially infectious materials include cerebrospinal fluid, pericardial fluid, amniotic fluid, synovial fluid, peritoneal fluid, and any fluid containing visible blood.

Risk Reduction and Prevention

Although the risk of contracting a communicable disease is real, it should not be exaggerated and certainly should not be a source of fear and stress. Fear comes from lack of proper education and training, and there is no reason an AEMT should not be properly educated about disease issues.

Standard Precautions

The **Occupational Safety and Health Administration (OSHA)** is the federal regulatory compliance agency that develops, publishes, and enforces guidelines concerning reducing risk in the workplace. All EMS personnel are required by OSHA to be trained in handling bloodborne pathogens and in approaching the patient who may have a communicable or infectious disease. Training must also be provided for issues including blood and body fluid precautions and **contamination** precautions.

Because health care workers are exposed to so many different kinds of infections, the **Centers for Disease Control and Prevention (CDC)** developed a set of **standard precautions** for health care workers to use when providing patient care. These protective measures are designed to prevent workers from coming in direct contact with germs carried by patients. The CDC recommendation is to assume that every person is potentially infected or can spread an organism that could be transmitted in the health care setting; therefore, you must apply infection control procedures to reduce infection

in patients and health care personnel.¹ **TABLE 2-1** summarizes the CDC recommendations.^{1,2} You must also notify your **designated officer** if you are exposed.

Safety

One of the most effective ways to control disease transmission is by washing your hands thoroughly with soap and water after any patient contact.

TABLE 2-1 Standard Precautions for the Care of All Patients in All Health Care Settings

Component	Recommendation
Hand hygiene	• Before, after, and between patient contacts • After touching blood, body fluids, secretions, excretions, or contaminated items • Immediately after removing gloves or other PPE
Personal Protective Equipment	
Gloves	• For touching blood, body fluids, secretions, excretions, or contaminated items • For touching mucous membranes and nonintact skin
Gown	• During procedures and patient care activities when contact of the AEMT's clothing/exposed skin to blood, body fluids, secretions, excretions, or contaminated items is anticipated
Mask, eye protection, face shield	• During procedures and patient care activities likely to generate splashes or sprays of blood, body fluids, secretions, or excretions; examples include suctioning or endotracheal intubation • These protections are especially important during respiratory disease outbreaks such as the COVID-19 pandemic.
HEPA respirator	• Use when working with a patient with tuberculosis or any other respiratory illness, such as COVID-19
Patient Care Environment	
Soiled patient care equipment	• Handle in a manner that prevents transfer of microorganisms to others and to the environment • Wear gloves if visibly contaminated • Hand hygiene
Environmental controls	• Have procedures for the routine care, cleaning, and disinfection of environmental surfaces • Special attention to frequently touched surfaces within the ambulance (handrails, seats, cabinets, doors) • Have patients with tuberculosis or COVID-19 wear a surgical mask
Textiles and laundry	• Handle in a manner that prevents transfer of microorganisms to others and to the environment
Needles and other sharp objects	• Do not recap, bend, break, or hand-manipulate used needles • Use safety features when available (needleless IV systems) • Place sharps in puncture-resistant containers

Component	Recommendation
Special Circumstances	
Patient resuscitation	• Use a resuscitation bag or other ventilation device to prevent contact with mouth and oral secretions • If COVID-19 is suspected, use a bag-mask device with a HEPA filter
Respiratory hygiene/cough etiquette	• Instruct symptomatic patients to cover the mouth/nose when sneezing or coughing • Use tissues and dispose of them in a no-touch receptacle • Perform hand hygiene after touching tissues • Place surgical mask(s) on the patient/provider • If a mask cannot be used, maintain special separation if possible

Modified from: Infection control: isolation precautions. Centers for Disease Control and Prevention website. <https://www.cdc.gov/infectioncontrol/guidelines/isolation/index.html/Isolation2007.pdf>. Reviewed July 22, 2019. Accessed December 30, 2020.

Donning and Doffing Full PPE

Putting on (donning) and taking off (doffing) the full complement of PPE in a consistent sequence is essential to reduce the risk of contamination. Although there are some variations, and additional PPE used in certain situations, the most common components of PPE are a mask, eyewear, gloves, and gown. To ensure proper donning and doffing, have a partner observe and assist with the process, or practice in front of a mirror. Always don the PPE in the same order based on your departmental policies. Regardless of the process used to doff PPE, the mask is the last PPE to be removed.

Donning PPE

Apply the gown and secure the ties at the neck and waist. Then put on the N95 mask, ensuring there is a tight seal. Don appropriate wraparound eyewear, goggles, or a face shield next, to protect your eyes. Gloves are donned last. Be sure to pull the cuffs up and over the sleeves of your gown.

Doffing PPE

Remove PPE carefully to ensure you do not contaminate yourself. Take off the gloves as described previously and discard. Remove eye protection from the back, tilting it forward to remove; decontaminate it later. Next, remove the gown by reaching around and untying it or breaking the ties. Pull your arms out while pulling the gown inside out, being careful not to touch the contaminated side of the gown. Discard the gown and then clean your hands with an alcohol-based hand sanitizer. To remove

the mask, reach around the back and pull the bottom strap over your head; then remove the top strap to pull the mask away from your face and discard it. Clean your hands again thoroughly.

Proper Hand Hygiene

Proper handwashing is perhaps one of the simplest, yet most effective, ways of controlling disease transmission. You should always wash your hands before and after contact with a patient, regardless of whether you wore gloves. The longer the germs remain with you, the greater their chance of getting through your barriers. Although soap and water are not protective in all cases, in certain cases their use provides excellent protection against further transmission from your skin to others (cross-contamination).

If no running water is available, you may use waterless handwashing substitutes (**FIGURE 2-3**). If you use a waterless substitute in the field, make sure that you wash your hands as soon as possible.

Follow the steps shown in **SKILL DRILL 2-1** for proper handwashing.³

Gloves

Gloves and eye protection are the minimum standard for all EMS personnel. Vinyl, latex, and nitrile gloves provide adequate protection. Your department may prefer one type of glove over the other, or you may choose the glove. You should evaluate each situation and choose the glove that works best. Some people are allergic to latex. If you suspect that you are, consult your supervisor for options. Vinyl gloves, which are less durable than the other materials, may

be best for routine procedures, and latex or nitrile gloves may be best for invasive procedures.

In some cases, you may be exposed to large volumes of blood or body fluids. Wearing double gloves may reduce your chance of exposure. In the course of routine care, gloves may receive minor punctures or tears without your knowledge. In these instances, wearing a second pair provides an additional layer

FIGURE 2-3 Use a waterless handwashing solution if there is no running water available. Be sure to wash your hands with soap once you arrive at the hospital.

© JOE CICAK/iStock/Getty Images Plus/Getty Images.

of protection.⁴ Also, if the outer gloves become visibly contaminated, you can remove the outer gloves before continuing with patient care or before donning and doffing PPE.⁵ Be sure to change gloves as you move from one patient to another. For cleaning and disinfecting the unit, you should use heavy-duty utility gloves (**FIGURE 2-4**). You should never use lightweight latex or vinyl gloves for cleaning.

FIGURE 2-4 Use heavy-duty utility gloves to clean the unit. You should never use lightweight latex or vinyl gloves for cleaning.

© Jones & Bartlett Learning.

Skill Drill 2-1 Handwashing

Step 1

Apply soap to hands. Rub hands together for at least 15 seconds to work up a lather. Pay particular attention to your fingernails. Rinse both hands using warm water.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 2

Dry your hands with a paper towel and use the paper towel to turn off the faucet.

Change gloves if they have been exposed to motor oil, gasoline, or any petroleum-based product. Do not perform tasks such as using a radio, driving, writing a patient care report, or using any monitoring device such as a cardiac monitor or pulse oximeter when wearing contaminated gloves.

Removing used latex or vinyl gloves requires a methodical technique to avoid contaminating yourself with the materials from which the gloves have protected you (**SKILL DRILL 2-2**).

Gloves are the most common type of **personal protective equipment (PPE)**. In many EMS rescue

Skill Drill 2-2 Proper Glove Removal Technique

Step 1

Begin by partially removing one glove. With the other gloved hand, pinch the first glove at the wrist, making sure to touch only the outside of the first glove, and start to roll it back off the hand, inside out. Leave the exterior of the fingers on the first glove exposed.

Step 2

Use the partially gloved fingers to pinch the wrist of the second glove and begin to pull it off, rolling it inside out toward the fingertips as you did with the first glove.

Step 3

Continue pulling the second glove off until you can pull the second hand free.

Step 4

With your now-ungloved second hand, grasp the exposed inside of the first glove and pull it free of your first hand and over the now-loose second glove. Be sure that you touch only clean, interior surfaces with your ungloved hand.

FIGURE 2-5 Wear eye protection to prevent blood splatter into your eyes.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

operations, you must also protect your hands and wrists from injury. You may wear puncture-proof leather gloves, with latex gloves underneath. This combination will allow you free use of your hands with added protection from blood and body fluids. Remember that latex or vinyl gloves are considered medical waste and must be disposed of properly. Leather gloves must be treated as contaminated material until they can be properly decontaminated.

Eye Protection

Eye protection is important in case blood or other fluid splatters toward your eyes (**FIGURE 2-5**). If this is a possibility, wearing goggles is your best protection. People who wear prescription eyeglasses will also need additional protection for their eyes, as prescription eyeglasses offer little side protection. Obviously, contact lenses offer no added protection from splashing. Face shields will also provide good eye protection (**FIGURE 2-6**).

Safety

Due to the highly infectious nature of coronavirus disease 2019 (COVID-19), eye protection should be used when caring for all patients known or suspected to be infected with this virus.

FIGURE 2-6 The surgical mask/face shield combination.

© Dr. P. Marazzi/Science Source.

Gowns

Occasionally, you may need to wear a gown. When used together with other PPE, a gown provides good protection from extensive blood splatter. Gowns may be worn in situations such as field delivery of an infant or major trauma. However, wearing a gown may not be practical in many situations. Your department will likely have a policy regarding gowns. Be sure you know your local policy. There are times when a change of uniform is preferred because trying to clean off contaminants is difficult and sometimes impossible without professional cleaning and disinfection or disposing of the uniform entirely.

Masks, Respirators, and Barrier Devices

The use of masks is a complex issue, especially given OSHA and CDC requirements regarding protection from infectious respiratory illnesses. You should wear a standard surgical mask if blood or body fluid splatter is a possibility. If you suspect that a patient has an airborne disease, you should place a surgical mask on the patient. However, if you suspect that the patient has **tuberculosis** or influenza, or in a situation such as the COVID-19 pandemic, place a surgical mask on the patient and a high-efficiency particulate air (HEPA) respirator on yourself (**FIGURE 2-7**). Protective eyewear such as safety glasses with side shields, goggles, or an

FIGURE 2-7 Wear a high-efficiency particulate air respirator if you treat a patient whom you suspect has tuberculosis or COVID-19.

© European Centre for Disease Prevention and Control (ECDC) 2020.

approved face shield is also needed. If the patient needs oxygen, apply a nonrebreathing mask with an oxygen flow rate of 10 to 15 L/min instead of a surgical mask. Do not place a HEPA respirator on the patient; it is unnecessary and uncomfortable. A simple surgical mask will reduce the risk of transmission of germs from the patient into the air. Use of a HEPA respirator should comply with OSHA standards, which state that facial hair, such as long sideburns or a mustache, will prevent a proper fit.⁶

Although there are no documented cases of disease transmission to rescuers as a result of performing unprotected mouth-to-mouth resuscitation on a patient with an infection, you should use a pocket mask with a one-way valve or bag-mask device (**FIGURE 2-8**). Bag-mask ventilation is an aerosol-generating procedure and should be performed with the use of an inline HEPA filter in epidemic scenarios such as COVID-19.

Remember that the outside surfaces of these items are considered contaminated after they have been exposed to the patient. You must ensure that gloves, masks, gowns, and all other items that have been exposed to infectious processes or blood are properly disposed of according to local guidelines. If you are stuck by a needle, get blood or other body

FIGURE 2-8 Barrier devices such as a pocket mask are necessary when providing artificial ventilations.

© Bart_/Shutterstock.

fluid in your eye, or have contact with any body fluid from the patient, seek medical care as soon as it is feasible and report the incident to your supervisor.

Words of Wisdom

Aerosol-generating procedures (AGPs) are treatments that increase the risk for transmission of infections that are spread through the air or by droplets. During an AGP, small particles and droplets from the patient's respiratory tract become airborne. Nearby EMS providers who are not wearing appropriate PPE can inhale those particles or droplets or get them into their eyes or mouth, thereby exposing them to viruses or bacteria. When a patient has an infectious respiratory disease, or in situations of community spread of communicable diseases, AGPs pose a high risk for caregivers. Examples of AGPs include cardiopulmonary resuscitation (CPR) and some basic and advanced airway procedures.

Proper Disposal of Sharps

Be careful when handling needles, scalpels, and other sharp items. The spread of HIV and hepatitis in the health care setting can usually be traced to careless handling of sharps. Preventive measures

FIGURE 2-9 Properly dispose of sharps in a closed, rigid, marked container.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

to help you reduce the number of needlestick and sharps injuries include the following:⁷

- Do not recap, break, or bend needles. Even the most careful people may stick themselves accidentally.
- Use needleless systems and IV catheters with safety systems when available.
- Ensure that sharps containers are within easy reach.
- Immediately dispose of all sharp items that have been in contact with human secretions in approved, closed, puncture-proof containers **FIGURE 2-9**. Such containers are labeled with a biohazard insignia.

Employer Responsibilities

Your employer cannot guarantee a 100% risk-free environment. Taking the risk of **exposure** to a communicable disease is a part of your job. You have a right to know about diseases that may pose a risk to you. Remember, however, that your risk for infection is not high; however, OSHA regulations, especially for private and federal agencies, require that all employees be offered a workplace environment that reduces the risk for exposure.⁸ Note that in some states that have their own OSHA plans, state and municipal employees must also be covered.

In addition to OSHA guidelines, other national guidelines and standards, including those from the CDC and National Fire Protection Association (NFPA) 1581, *Standard on Fire Department Infection Control Program*, address reducing the risk

for exposure to bloodborne pathogens (disease-causing organisms) and airborne diseases.⁹ These agencies set a standard of care for all fire and EMS personnel and apply whether you are a full-time paid employee or a volunteer. It is your responsibility to know your department's infection control plan and to use it (**TABLE 2-2**).

Establishing an Infection Control Routine

Infection control, or the use of procedures to reduce infection in patients and health care personnel, should be an important part of your daily routine. For example, good hand hygiene is always necessary. Typically, gloves will be used for all patient contacts.

Remember to change gloves and wash hands between patients. If you or your partner is exposed while providing care, try to relieve each other as soon as possible so that you can seek care and notify the designated officer to report the incident. Follow the steps in **SKILL DRILL 2-3** to prevent potential exposure situations.

Be sure to routinely clean the ambulance after each run and on a daily basis. Cleaning is an essential part of the prevention and control of communicable diseases and will remove surface organisms that may remain in the unit. Address the high-contact areas, including surfaces that were in direct contact with the patient's blood or body fluids or surfaces that you touched while caring for the patient after having contact with the patient's blood or body fluids.

Whenever possible, cleaning should be done at the hospital. If you clean the unit back at the station, make sure you have a designated area with good ventilation and a floor drain. Any medical waste should be put in a red bag and disposed of at the hospital whenever possible. Any contaminated equipment that is left with the patient at the hospital should be cleaned by hospital staff or bagged for transport and cleaned at the station.

You can use a bleach and water solution at a 1:10 dilution to clean the unit.¹⁰ The solution you mix should not have a strong odor of bleach if mixed correctly. A hospital-approved disinfectant that is effective against *Mycobacterium tuberculosis* can also be used. Use the cleaning solution in a bucket or pistol-handled spray container. When

TABLE 2-2 Components of an Infection Control Plan

Determination of exposure	• Determines who is at risk for ongoing contact with blood and other body fluids • Creates a list of tasks that pose a risk for contact with blood or other body fluids • Includes PPE required by OSHA
Education and training	• Explains why a qualified person is required to answer questions about communicable diseases and infection control, rather than relying on packaged training materials • Includes availability of an instructor able to train AEMTs regarding bloodborne and airborne pathogens, such as hepatitis B and C viruses, HIV, and the bacteria that cause diseases such as syphilis and tuberculosis • Ensures that the instructor provides appropriate education, which is the best means for correcting many myths surrounding these issues
Hepatitis B vaccine program	• Describes the vaccine offered, its safety and efficacy, record keeping, and tracking • Addresses the need for postvaccine antibody titers to identify people who do not respond to the initial three-dose vaccination series
Personal protective equipment	• Lists the PPE offered and why it was selected • Lists how much equipment is available and where to obtain additional PPE • States when each type of PPE is to be used for each risk procedure
Cleaning and disinfection practices	• Describes how to care for and maintain vehicles and equipment • Identifies where and when cleaning should be performed, how it is to be done, what PPE to use, and which cleaning solution to use • Addresses medical waste collection, storage, and disposal
Tuberculin skin testing/fit testing	• Addresses how often employees should undergo tuberculin skin testing (PPD) • Addresses how often fit testing should be done to determine the proper size HEPA mask to protect the AEMT from tuberculosis • Addresses all issues dealing with HEPA respirator masks
Postexposure management	• Identifies who to notify when exposure may have occurred, forms to be filled out, where to go for treatment, and which treatment is to be administered
Compliance monitoring	• Addresses how the service or department evaluates employee compliance with each aspect of the plan • Ensures that employees understand what they are to do and why it is important • States that noncompliance should be documented • Indicates what disciplinary action should be taken in the face of noncompliance
Record keeping	• Outlines all records to keep, how confidentiality will be maintained, and how, when, and by whom records can be accessed

Abbreviations: AEMT, advanced emergency medical technician; HEPA, high-efficiency particulate air; HIV, human immunodeficiency virus; OSHA, Occupational Safety and Health Administration; PPD, purified protein derivative; PPE, personal protective equipment

© Jones & Bartlett Learning.

using commercially prepared disinfectants, pay attention to manufacturer directions.

Remove contaminated linen and place it into an appropriate bag for handling. Each hospital may have a different system for handling contaminated linen; you should learn hospital or department protocols (**FIGURE 2-10**).

Any reusable medical equipment should be properly cleaned and sanitized or sterilized per

your department's standard operating procedures. Keep in mind that in hospitals, entire departments are devoted to sterilizing medical instruments. Proper sterilization requires the right tools and the right skills; follow your department's procedures. Discard all disposable equipment that was used in the care of the patient and meets the definition of medical waste as dictated by your state in an appropriate receptacle.

Skill Drill 2-3 Preventing a Potential Exposure

Step 1

En route to the scene, make sure that PPE is out and available.

Step 2

On arrival, make sure the scene is safe to enter, and perform a 60- to 90-second rapid exam of the patient, noting whether any blood or body fluids are present. Select the proper PPE according to the tasks you are likely to perform. Limit the number of people who are involved in patient care.

© Jones & Bartlett Learning.

YOU are the Provider

Part 2

After you ensure that you and your partner have on the appropriate PPE, your partner performs a rapid exam of the patient and finds only lacerations to each arm as a result of broken glass. You do a 360° survey of the vehicle and find that it is leaking unknown fluids onto the ground. You proceed to contact your dispatch to have the local fire department and law enforcement respond to the scene.

Recording Time: 1 Minute

Appearance	Calm
Level of consciousness	Alert and oriented to person, place, time, and event
Airway	Patent
Breathing	Nonlabored
Circulation	Strong radial pulses; skin warm and dry

4. Does the fire department need to be informed of the patient's HIV-positive status?

FIGURE 2-10 Contaminated linen should be bagged appropriately and disposed of according to your local protocols.

© Jones & Bartlett Learning.

Learn the regulations defining medical waste in your area. The procedures for disposal of infectious waste such as needles and heavily soiled dressings may vary from hospital to hospital and from state to state. More information about the steps to take, including how to decontaminate your ambulance and equipment during the postrun phase, can be found in Chapter 39, *Transport Operations*.

Words of Wisdom

To avoid unnecessary delays in treatment, ensure that you are wearing proper PPE when you reach the patient.

Immunity

Even if pathogens do reach you, they may not infect you because you may be **immune**, or resistant, to those particular germs. Immunity is a major factor in determining which hosts become ill from which germs (**TABLE 2-3**). One way to gain immunity from

many diseases today is to be immunized, or vaccinated, against them. Vaccinations have almost eliminated some childhood diseases, such as measles and polio.

Words of Wisdom

The first vaccines to protect against COVID-19 infection were approved for use in the United States in December 2020. Although vaccine development for a new viral strain typically takes 1 decade or longer, the process was expedited in response to the COVID-19 pandemic, both by allocating vast resources to the vaccines' development and by capitalizing on research already completed on similar strains of the coronavirus.

Another way in which the body becomes immune to a disease is to recover from an infection from that germ. Afterward, the body will recognize and repel that germ when it shows up again. Once exposed, healthy people will develop lifelong immunity to many common pathogens. For example, a person who contracts and becomes infected with the hepatitis A virus may be ill for several weeks, but because immunity will develop, the person will not have to worry about getting the illness again. Sometimes, however, the immunity is only partial. Partial immunity protects against new infections, but germs that remain in the body from the first illness may still be able to cause the same disease again when the body is stressed or has some impairment in its immune system. For example, tuberculosis can cause a mild, unnoticeable infection before the body builds up a partial immunity. If the infection is never treated, it may be reactivated when immunity is weakened; however, people with partial immunity are protected against a new infection from another person.

Humans seem unable to mount an effective immune response to some infections, such as HIV infection, which can progress to acquired immunodeficiency syndrome (AIDS). HIV is a virus that attacks the immune system and weakens the body's ability to fight infections. Because the immune system is our natural defense, the body is unable to fight off disease if it is not strong.

Remember, germs that cause no symptoms in one person may cause serious illness in another.

TABLE 2-3 Immunity to Infectious Diseases

Type of Immunity	Characteristics	Examples	Comments
Lifelong	The illness will not recur.	Measles Mumps Polio Rubella Hepatitis A Hepatitis B	Infection or vaccination provides long-term immunity to new infection. A live vaccine is required for measles only.
Partial	The person who has recovered from a first infection is unlikely to get a new infection from another person, but may experience illness from germs that lie dormant from the initial infection.	Chickenpox Tuberculosis	Infection provides lifelong immunity to the patient from acquiring a new infection, but the original illness may recur, or it may recur in a different way. In the case of chickenpox, which is caused by the herpes zoster virus, an infection may recur years later in the form of shingles.
None	Exposure confers no protection from reinfection. The infection may wear down the patient's resistance.	Gonorrhea Syphilis HIV infection	No vaccine is available. Repeated infections are common. For example, there is effective immediate treatment for gonorrhea, and the germs may be eradicated; however, reinfection is likely if the high-risk practices continue (eg, unprotected sex). For syphilis and HIV infection, the lack of immunity allows the germs to continue to cause damage within the host.
Other/Unknown	Some viruses change from year to year, making it difficult to develop vaccines or innate immunity. In other cases virus strains are new, and little is known about them.	Influenza Coronavirus	Although a vaccine is available for influenza, researchers must predict which strains will be prevalent 1 year or more in advance. This means that if a new strain occurs, the vaccine will not provide full protection in the community. The COVID-19 pandemic was caused by a coronavirus strain. Initially there was no vaccine for it, but scientists drew on what they knew of other coronavirus strains and quickly developed a vaccine to address this new disease. It takes time to know if having the disease, or receiving the vaccine, confers temporary or lifelong immunity to COVID-19.

Abbreviation: COVID-19, coronavirus disease 2019; HIV, human immunodeficiency virus

Immunizations

As an AEMT, you are at risk for acquiring an infectious or communicable disease. Using basic protective measures can minimize the risk. You are responsible for protecting yourself.

Prevention begins by maintaining your personal health. EMS personnel should receive annual

health examinations. A history of all your childhood infectious diseases should be recorded and kept on file. Childhood infectious diseases include chickenpox, mumps, measles, rubella, and whooping cough. If you have not had one of these diseases, you must be immunized.

The CDC and OSHA have developed requirements for protection from bloodborne pathogens

such as the hepatitis B virus.^{11,12} An immunization program should be in place in your EMS system. Immunizations should be kept up-to-date and recorded in your file. Recommended immunizations include the following:

- Tetanus, diphtheria, pertussis (Tdap) boosters (every 10 years)
- Measles, mumps, and rubella (MMR) vaccine
- Influenza vaccine (yearly)
- Hepatitis B vaccine (as required by OSHA)
- Varicella (chickenpox) vaccine or having had chickenpox

Note that pregnant AEMTs need to get a dose of the Tdap vaccine during each pregnancy. Health care workers who are routinely exposed to meningitis should receive one dose of meningococcal vaccine.¹³

Although OSHA does not require hepatitis A immunization, you may want to be vaccinated as a preventive measure. Hepatitis A vaccination is not necessary if you have had hepatitis A in the past. All these vaccines are effective and rarely cause side effects. Many EMS systems require you to show proof that you are up-to-date with your immunizations.

Special Populations

Infants and small children, because of their relatively immature immune systems, are especially susceptible to infectious diseases. Pediatric immunizations prevent disease in children who receive them and protect those who come in contact with unvaccinated people. Although vaccine-preventable diseases have decreased in the United States, the viruses and bacteria that cause them still exist. According to the CDC, all children should be immunized against the following diseases:^{14,15}

- Measles, mumps, and rubella (MMR)
- Diphtheria, pertussis, and tetanus (DTaP)
- Chickenpox (varicella)
- Hepatitis A virus (HAV)
- Hepatitis B virus (HBV)
- Polio (inactivated polio vaccine; IPV)
- Haemophilus influenzae type b (Hib)
- Pneumococcal virus (PCV)
- Rotavirus (RV)
- Human papillomavirus (HPV)
- Flu (annual vaccine)
- Meningococcal virus

You should also have a skin test for tuberculosis before you begin working as an AEMT. The purpose of this test is to identify anyone who has been exposed to tuberculosis in the past. Testing should be repeated every year. It is important to know that testing positive on a tuberculosis skin test does not mean that you contracted the disease; rather, it simply indicates that you have been exposed. Additional follow-up will be needed to determine whether the disease is active. Another vaccine being investigated is for *Staphylococcus aureus*. This vaccine is not currently recommended, but may be soon.

If you know that you will be transporting a patient who has a communicable disease, you have a definite advantage. This is when your health record will be valuable. If you have already had the disease or been vaccinated, you are not at risk. However, you will not always know whether a patient has a communicable disease. Therefore, always take standard precautions if there is the possibility of exposure to blood or other body fluids.

General Postexposure Management

The likelihood of becoming infected during your performance of routine patient care is low. In the event that you are exposed to blood or other body substances despite all of your precautions, there are still preventive measures that you can take to protect your health. If you are exposed to a patient's blood or body fluids, first turn over patient care to another EMS provider. When it is safe to do so, clean the exposed area with soap and water. If your eyes were exposed, rinse them with water for at least 20 minutes as soon as possible.

Safety

In the event of exposure involving the eyes, immediately flush with sterile water or saline for at least 20 minutes.

Next, activate your department's infection control plan. This usually involves contacting a supervisor or your department's infection control officer to assist you. This person will help you to navigate the infection control process.

You will need to be screened to determine if there was a significant exposure to possible blood-borne pathogens. Just because you were exposed to a patient's blood or body fluids does not mean that there is a risk of infection. Typically, you will need a follow-up evaluation by a physician to determine if a significant exposure occurred. If the exposure was significant, blood may need to be drawn from both you and the patient to determine if any infectious agents were present.

You will have to complete a postexposure report. Questions in the report may include: When did the event happen? What were you doing when you were exposed? What did you do after you were exposed? Completion of this paperwork will help relay critical information to the right people, resulting in help for you and possibly new protocols in the future to help prevent another incident.

Time is important! If you are exposed, let your supervisor or infection control officer know immediately. Some diseases will act quickly whereas others may lie dormant for a long time. The best way to reduce your risk of contracting a work-related disease is through early activation of your department's infection control plan.

In the case of diseases spread in the air or by droplets, you may not realize you have been exposed to the disease until the hospital notifies you. If you were wearing full PPE with gloves, gown, eye protection, and N95 mask, no further follow-up may

be needed. In other cases, specific postexposure care or prophylaxis may be indicated. In the event that you have been exposed to a highly communicable airborne disease such as COVID-19 without proper PPE, you may be required to quarantine for a predetermined time (usually 10–14 days). During that time, public health officials may require you to report your temperature and other symptoms daily.

Words of Wisdom

The ability of your EMS system to support you in case of exposure to a communicable disease depends on your understanding of how exposure can occur and your immediate report of exposure to potentially infectious materials. Document the event as soon as possible to ensure that you remember all pertinent information, and make a report immediately after the exposure, following your service's guidelines.

Postexposure Prophylaxis and Treatment for Significant Exposure

The last defense for an AEMT who has a significant exposure to an infectious disease is postexposure preventive measures or treatment. Unfortunately, these are not available for all diseases and are offered only if an investigation determines that you have

YOU are the Provider

Part 3

The patient denies having any head, neck, or back pain, stating that his cell phone rang and as he answered it, he swerved and rolled his vehicle. You inform the patient that he will require full spinal immobilization, which he promptly refuses. The patient states that he just wants to be "bandaged up" and left on scene.

Recording Time: 4 Minutes

Respirations	18 breaths/min, normal
Pulse	Strong and regular, 82 beats/min
Skin	Warm and dry
Blood pressure	124/86 mm Hg
Oxygen saturation (Spo₂)	100% on room air
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

5. Does this patient have the right to refuse care?

had a significant exposure. Postexposure treatment for HIV includes treatment with a specific combination of antiretroviral medications. In the case of hepatitis B exposure, you will be tested to see if you already have antibodies if you have been vaccinated for the disease. If you have antibodies, no treatment is needed. If you do not have antibodies, you will receive an injection with hepatitis B immune globulin, which contains antibodies that will attack the virus in your body. However, this injection confers only temporary protection, so it is followed up with the series of three hepatitis B immunization shots. There is no treatment to prevent you from getting hepatitis C infection after an exposure.

Postexposure treatment for tuberculosis will not begin unless your tuberculin skin test is positive during the monitoring period. In this case, a long period of treatment with oral anti-tuberculin medicines will begin.

There are very few infectious exposures for which you will receive antibiotics. Significant exposure to pertussis and some types of bacterial meningitis would be included.

Street Smarts

You should be aware of the procedures you are required to follow if you are involved in an exposure during your clinical or field experience. If you do not know, ask your instructor.

Illness and Injury Prevention

Grouping injuries into common health problems makes it possible to consider the breadth and depth of the problem and has enabled public health officials and other health care providers to call attention to important problems and target more effective interventions. Intentional injuries, such as assault or suicide, is one group of injuries. EMS can play a role in preventing intentional injuries, but can usually have a greater impact in preventing unintentional injuries.

How big of a problem are injuries in the United States? To many health experts, they are the largest public health problem facing the country today. **TABLE 2-4** shows the top 10 causes of death in the United States in 2017.¹⁶ This information is important in understanding how injury has an impact on

TABLE 2-4 Top 10 Causes of Death in 2017

1. Heart disease
2. Cancer
3. Unintentional injuries
4. Chronic, lower respiratory disease
5. Stroke
6. Alzheimer disease
7. Diabetes
8. Influenza and pneumonia
9. Kidney disease/renal disease
10. Suicide

Data from: Centers for Disease Control and Prevention. 10 Leading Causes of Death by Age Group, United States—2017. https://www.cdc.gov/injury/wisqars/pdf/leading_causes_of_death_by_age_group_2017-508.pdf. Accessed December 30, 2020.

different age groups. From ages 1 to 44 years, unintentional injuries are the leading cause of death.¹⁷ For all ages combined, unintentional injuries are the third leading killer behind heart disease and cancer.¹⁶

It is easier to measure death rates than to measure nonfatal injury rates because visits to clinics, emergency departments, physicians' offices, and other places for treatment are scattered among many agencies and professional groups. According to the CDC, each year, more than 139 million people will judge their medical condition to be severe enough to seek treatment in an emergency department; more than 40 million of those visits are for injuries.¹⁸

Words of Wisdom

There are many prevention strategies that an AEMT can be involved in. Patient education can help prevent injuries from occurring. EMS providers are in a good position to recognize signs and symptoms of suspected abuse and abusive situations. When EMS providers recognize such signs, they can report these suspicions to local law enforcement or other appropriate authorities. EMS providers can also refer patients to care and rehabilitation services, to help prevent further problems as a result of an event that has already occurred. Such services may include child protective services; shelters for sexual, spousal, or elder abuse; food; clothing; counseling; alternative sources of health care such as free clinics; grief support; and numerous others. Keeping a list of resources or a few pamphlets from a local shelter in your ambulance can be very beneficial in a time of crisis.

Another factor to consider is the early release of patients from hospitals. Whether the reason is insurance restrictions or physician discretion, the outcome is the same: an increased number of at-risk patients for EMS providers to manage.

In most areas, EMS providers are considered high-profile role models. They generally reflect the composition of the community and, in a rural setting, may be the people with the most medical education. EMS providers are often considered advocates of the injured or ill and, as such, are welcomed into schools and other environments. They are considered authorities on injury and prevention.

Special Populations

With a growing geriatric population, a good fall prevention program may be one of the keys to preventing an overload of the health care system. Evaluate all community options available to the older population in your area and bridge any gaps with programs to meet their needs and prevent injuries related to falls.

Scene Safety and Personal Protection

The personal safety of all people involved in an emergency situation is very important. In fact, it is so important that the steps you take to preserve personal safety must become automatic. Anticipate danger based on the type of scene you are about to enter. Drivers who gawk at the scene of a crash may run into you or another vehicle. A second accident at the scene or an injury to you or your partner creates more problems, delays emergency medical care for patients, increases the burden on the other AEMTs, and may result in unnecessary injury or death.

You should begin protecting yourself as soon as you are dispatched. Before you leave for the scene, begin preparing yourself both mentally and physically. Make sure you wear seat belts and shoulder harnesses en route to the scene. Also be sure to wear seat belts and shoulder harnesses at all times during transport unless patient care makes it impossible (**FIGURE 2-11**). It is also important to ensure that all equipment is restrained so it does not become a hazard to you or the patient during

FIGURE 2-11 Wear seat belts and shoulder harnesses en route to the scene.

transport. Finally, remember to don the appropriate PPE prior to departing the ambulance when you arrive on scene.

Protecting yourself at the scene is also very important. A second accident may damage the ambulance and may result in injury to you or your partner or additional injury to the patient. To prevent this kind of event, crash scenes must be well marked. If law enforcement has not already done so, you should make sure that proper warning devices are placed a sufficient distance from the scene. This will alert motorists coming from both directions that a crash has occurred. You should park the ambulance at a safe but convenient distance from the scene. Before attempting to access patients trapped in a vehicle, check the vehicle's stability, and then take any necessary measures to secure it. Do not rock or push on a vehicle to find out whether it will move; this can overturn the vehicle or send it crashing into a ditch. If you are uncertain about the safety of a crash scene, wait for appropriately trained personnel to arrive before approaching.

When working at night, you must have plenty of light. Poor lighting increases the risk of further injury to you and the patient. It also results in poor emergency medical care. The ANSI (American National Standards Institute) and the ISEA (International Safety Equipment Association) require EMS personnel to wear reflective vests or clothing that meet Class 2 or 3 standards on roadways. You can also wear emblems or clothing to help make you more visible at night and decrease your risk of injury (**FIGURE 2-12**).

FIGURE 2-12 Wear reflective emblems or clothing to help make you more visible at night and improve your safety in the dark.

© Glen E. Ellman.

Words of Wisdom

According to the Bureau of Labor Statistics, approximately 4.1 million serious injuries and 4,500 deaths occur in US workplaces, with a direct cost of more than \$50 billion each year. EMS providers visit EDs for work-related injuries and exposures over 20,000 times each year.¹⁹ As an AEMT, you are most at risk for sprains and strains, exposures to blood and body fluids, and falls. Simple measures such as practicing safe lifting, using appropriate PPE, and wearing slip-resistant footwear can reduce the incidence of these visits.

Scene Hazards

During your career, you will be exposed to many hazards. Some situations will be life threatening. In these cases, you must be properly protected, or you must avoid the hazard completely.

Hazardous Materials

Your safety is the most important consideration at a hazardous materials incident. On arrival, you should look at the scene and try to read any labels, placards, and identification numbers from a distance, perhaps using binoculars. Placards are used on transportation vehicles and buildings, and labels are used on individual packages containing hazardous materials (hazmat). The placards are colored and diamond-shaped. The Department of Transportation (DOT) *Emergency Response Guidebook* is an important resource.²⁰ It lists most hazardous materials and the proper procedures for scene control

FIGURE 2-13 The Department of Transportation *Emergency Response Guidebook* is available as a mobile app that lists many hazardous materials and the proper procedures for scene control and emergency care of patients.

Courtesy of the U.S. Department of Transportation.

and emergency care of patients. Several similar resources are also available. In addition, some state and local government agencies may have information about the hazardous materials in their areas. A copy of the guidebook (which is now also available as a mobile app) and other information relevant to your area should be available in your unit or at the dispatch center (**FIGURE 2-13**).²¹

Always maintain a high index of suspicion when approaching a scene with a placard or label. Remember, some hazardous materials may not be marked properly. A specially trained and equipped hazardous materials team will be called to handle disposal of materials and removal of patients. You

Safety

AEMTs should be aware of the potential hazards that may be present when responding to the scene. The best protection when hazards are present is early recognition that a hazard may exist. Remember that scenes are dynamic and have the potential to become dangerous at any time, even if they may appear safe initially.

should not begin caring for patients until they have been moved away from the scene or the scene is safe for you to enter. For more information on recognizing a hazmat situation, see Chapter 40, *Vehicle Extrication, Special Rescue, and Hazardous Materials*.

Vehicle Crashes

The site of a vehicle collision can pose some of the most unstable and potentially lethal situations an EMS provider will face. Traffic hazards are the first risk to consider. As you drive your ambulance to the scene of a motor vehicle crash (MVC), it is important to keep several things in mind: What is the flow of traffic near and around the crash? How will you be able to safely leave and move about the scene? Ideally, you should park your ambulance in a manner where you can easily leave the scene. Keep in mind that additional fire, rescue, and police vehicles may be parked in the same area or may be blocking your exit. Hydraulic and hose lines are just two examples of common blockages you may encounter.

If you are the first to arrive at the scene, use the ambulance itself as a shield to protect the scene. The ambulance can be relocated for easier exit once additional help arrives. Park at least 100 feet (30 m) away from all crash sites.

As you approach the scene, be very conscious about the flow of traffic. If needed, request police assistance to shut down the roadway. This will ensure a safe scene as you work with patients.

When you are approaching damaged vehicles, look for signs of fluid leakage. Leaking fluids can be flammable, but a more common problem is slipping and sliding on the roadway.

Also look for signs of vehicle instability. How is the vehicle positioned? Is it stable? Motor vehicles can come to rest in a wide array of positions. As the center of gravity of the vehicle is raised, its ability to fall onto you increases. The standard approach for all MVCs should be for firefighters to first stabilize the vehicles to ensure safety for the passengers and any EMS providers.

Are there other hazards such as power lines? Downed lines can generate lethal electrical charges many feet away from MVCs. If there are lines down, you should assume they are power lines and not approach them. Call for additional resources to manage this hazard. Be aware that most electric companies will not shut power down to the grid.

Although this seems like a logical solution, how many injuries are caused by the unscheduled power outage? If people in their homes are on ventilators, shutting the power off could create another emergency situation.

With proper equipment and training, you may enter the vehicle itself. In the interior of the vehicle, airbags can be another hazard. If the airbag has not deployed, there is a risk that it may accidentally activate while you are in the vehicle, potentially injuring you and the patients. Maintain a safe distance from the airbags. For more information on operating safely inside patient vehicles, see Chapter 40, *Vehicle Extrication, Special Rescue, and Hazardous Materials*.

Your protective clothing will help you to remain safe while working in and around the MVC. The risk of injuries from glass and sharp metal objects cannot be underestimated. Make sure if you are working inside the vehicle, you have sufficient protective gear.

Electricity

Electrical shock can be produced by human-made sources (power lines) or natural sources (lightning). No matter what the source, you must evaluate the risk to yourself and to the patient before you begin patient care.

Power Lines

You should not touch downed power lines. Dealing with power lines is beyond the scope of AEMT training. However, you should mark off a danger zone around the downed lines with a perimeter of at least 35 feet. Energized, or “live,” power lines, especially high-voltage lines, behave in unpredictable ways. You need in-depth training to be able to handle the equipment that is used in an electrical emergency. The equipment also has specific storage needs and requires careful cleaning. Dirt or other contaminants can make this equipment useless or dangerous.

At the scene of an MVC, above-ground and below-ground power lines may become hazards. Disrupted overhead wires may or may not be a visible hazard. You must be careful even if you do not see sparks coming from the lines. Visible sparks are not always present in charged wires. The area around downed power lines is always a danger

zone—this danger zone extends well beyond the immediate accident scene.

Use the utility poles as landmarks for establishing the perimeter of the danger zone. The danger zone must be a restricted area. Remember, the safety zone is generally one span of the power pole's distance. Only emergency personnel, equipment, and vehicles are allowed inside this area.

Do not approach downed wires or touch anything that downed wires have come in contact with until qualified personnel have concluded that no risk of electrical injury exists. This may mean that you are unable to access a severely injured victim of an MVC even if you can see and talk to the person.

Lightning

Lightning is a complex natural phenomenon. You are unwise to think “lightning never strikes in the same place twice.” If the right conditions remain, a repeated strike in the same area can occur.

Lightning is a threat in two ways: through a direct hit and through ground current. After the lightning bolt strikes, the current drains along the earth, following the most conductive pathway. To avoid being injured by a ground current, stay away from drainage ditches, moist areas, small depressions, and wet ropes. If you are involved in a rescue operation, you may need to delay it until the storm has passed. Recognize the warning signs just before a lightning strike. As your surroundings become charged, you may feel a slight tingling sensation on your skin, or your hair may even stand on end. In this situation, a strike may be imminent. Move immediately to the lowest possible area.

If you are caught in an open area, try to make yourself the smallest possible target for a direct hit or for ground current. To keep from being hit by the initial strike, stay away from projections from the ground, such as a single tree. Drop all equipment, particularly metal objects that project above your body. Avoid fences and other metal objects, as they can transmit current from the initial strike over a long distance. Maintain a physical distance from others and position yourself in a low crouch. This position exposes only your feet to the ground current. By comparison, if you sit, both your feet and your buttocks are exposed. Place an object made of nonconductive material, such as a blanket, under your feet. Get inside a vehicle or your unit, if possible, as vehicles will protect you from lightning.

Safety

Recognize the warning signs before a lightning strike. You may feel a tingling sensation on your skin, or your hair may stand on end. Move immediately to a low-lying area. If caught in an open area, make yourself the smallest possible target.

Fire

You will often be called to the scene of a fire to care for victims or to stand by in anticipation of possible injuries to fire personnel on the scene. Therefore, you should understand some basic information about fire. There are seven common hazards in a fire:

1. Smoke
2. Oxygen deficiency
3. High ambient temperatures
4. Toxic gases
5. Building collapse
6. Equipment
7. Explosions

Smoke is made up of a variety of particles and gases, many of which are highly toxic. The particles irritate the respiratory system on contact. Most smoke particles become trapped in the upper respiratory system, but many smaller particles enter the lungs. In addition to causing airway irritation, some smoke particles may be deadly. Notably, many modern building materials contain nitrogen or halogens, and their burning results in the release of hydrogen cyanide and inorganic acids in fire smoke; these toxic by-products are major threats to health.²² You must be trained in the use of appropriate airway protection, such as a disposable short-term device, or, if you are a firefighter, a self-contained breathing apparatus, and have it available at all fire scenes (**FIGURE 2-14**).

Fire consumes oxygen, particularly in an enclosed space, making breathing difficult for anyone in that space. The high ambient temperatures in a fire can result in thermal burns and damage to the respiratory system. Breathing air that is heated to more than 120°F (49°C) can damage the respiratory system.

A typical building fire emits many toxic gases, including carbon monoxide, cyanide, and carbon dioxide. Carbon monoxide is a colorless, odorless

FIGURE 2-14 AEMTs who are also firefighters should be trained in the use of a self-contained breathing apparatus and have it available if they may be working near fire scenes.

Courtesy of Lance Cpl. Brian Kester/US Marines.

gas that is responsible for more fire deaths each year than any other by-product of combustion. Carbon monoxide has an affinity for hemoglobin that is 200 times greater than that of oxygen, so it blocks the ability of the hemoglobin to transport oxygen to your body tissues. Cyanide is a product of the combustion of many materials that burn. Inhaling cyanide prevents cells from using oxygen. In sufficiently high concentrations, it causes signs and symptoms of shock and severe hypoxia leading to death. Carbon dioxide is also a colorless, odorless gas. Exposure to this gas causes increased respirations, dizziness, and sweating. Breathing concentrations of carbon dioxide greater than 10% to 12% will result in death within a few minutes.

Words of Wisdom

Because of the high affinity of carbon monoxide for hemoglobin, a patient with carbon monoxide poisoning will have a high oxygen saturation reading while still experiencing extreme hypoxia. Measure end-tidal carbon dioxide levels to monitor all patients with possible carbon monoxide exposure.

During and after a fire, there is always a possibility that all or part of the burned structure will collapse. Often, there are no warning signs that collapse is imminent. Thus, you must be extremely cautious whenever you are near a burning structure

or one in which a fire has just been put out. As an EMS provider, you should never enter a burning building without proper breathing apparatus and approval. At any fire scene, follow the instructions of the incident commander and safety officer and never undertake any task (ie, enter a burning structure or initiate search and rescue) unless you have been properly trained to do so.

Fuel and fuel systems of vehicles that have been involved in crashes are also a fire hazard. A vehicle leaking fuel may ignite under the right conditions. If you see or smell a fuel leak or if people are trapped in the vehicle, you must coordinate the use of appropriate fire protection equipment.

Make sure that you are properly protected if there is or has been a fire in the vehicle. Wear appropriate respiratory protection and thermal protection because the smoke from a vehicle fire contains many toxic by-products. The use of appropriate protective gear at a crash scene can reduce your risk of injury. Avoid using oxygen in or near a vehicle that is smoking, smoldering, or leaking fuel.

Mass Violence

The safety of you and your team should always be your primary concern. Civil disturbances, domestic disputes, and crime scenes, especially those involving gangs, can create many hazards for EMS personnel. Scenes of mass violence such as shootings or bombings, civil disturbances, and large gatherings of hostile or potentially hostile people pose an even greater threat. Several agencies will respond to large civil disturbances. In these instances, it is important for you to know who is in command and will be issuing orders. However, you and your partner may initially be present at a scene at which a group of people subsequently grows larger and becomes increasingly hostile. In these cases, you should call law enforcement personnel immediately if they are not already at the scene. You may need to remove yourself from the scene and wait for law enforcement personnel to arrive and secure the scene before you can begin treatment or safely approach the patient.

Crime Scenes

A crime scene often poses potential problems for EMS personnel. A perpetrator who is still at the scene could reappear and threaten you and your

Words of Wisdom

In some cases, emergency responders might be the direct target of violence. The rate of violence-related injuries with work loss for emergency responders is 22 times higher than the overall rate for other employees in the United States.²³ Ensuring health and wellness in the face of violence against EMS providers demands strategies of prevention and strategies of protection.

Recommendations for the prevention of violence include the following:

- Training and practice in identifying scenes of potential violence
- Training and practice in deescalation strategies and techniques
- Training and practice to improve interpersonal communications
- Practice in ongoing scene assessment
- Dispatch identification and alerting of past or potential threats of violence

Recommendations for protection against violence include the following:

- Training and practice in self-defense and escape techniques
- Training and practice in physical and chemical restraint techniques
- Fitting and use of body armor
- Training and practice in operations with law enforcement personnel

If you experience physical or verbal violence, report it on the appropriate incident form. Follow your state laws and department policies to report instances of physical assault.

partner or attempt to further injure the patient you are treating. Bystanders who are trying to be helpful may interfere with your ability to provide emergency medical care. Family members may be distraught and not understand what you are doing when you attempt to splint an injured extremity and the patient cries out in pain. Be sure that you have adequate assistance from the appropriate public safety agency in these cases.

Words of Wisdom

If you believe that an event is a crime scene, you must attempt to maintain the chain of evidence. Make sure that you do not disturb the scene unless it is absolutely necessary in caring for the patient.

Remember that anytime you are on someone else's turf, that person has a clear advantage. You can expect that person to know everything about the environment while you know nothing (including the location of any weapons). Hostile patients in their home environment are much more dangerous there than anywhere else, especially in poor lighting. Always leave yourself an out; never allow someone to get between you and the exit.

Remember that your personal safety is of utmost importance. You must thoroughly understand the risks of each environment you enter. As part of sizing up the scene, evaluate it for the potential for violence. In some cases, especially if the violence has only just occurred, other responders may not be aware of the situation. In other cases, the dispatch information may not reflect the potential for violence at all. In these situations, you should call law enforcement immediately if they are not already present. Never enter an unstable environment, such as a shooting, a brawl, a hostage situation, or a riot.

If possible, call for additional resources when presented with a potentially dangerous scene. Failure to do so may put you and your partner at serious risk. Rely on the advice of law enforcement personnel because they have more experience and expertise in handling these situations. Whenever you are in doubt about your safety, do not put yourself at risk.

Words of Wisdom

Always keep loose hair pulled back and do not wear any loose jewelry. Loose hair, necklaces, and dangling earrings not only have the potential to get caught during the course of patient care, but also offer a hazard that allows for grabbing or pulling when dealing with a violent patient or one with an altered mental status.

Behavioral Emergencies

There are many potential causes of a behavioral emergency, ranging from physical causes (hypoglycemia, head injury) to psychiatric diseases. Although most behavioral emergencies do not pose a threat to you, the potential of threat to either the patient or yourself exists, and you should use caution. Consider these questions as you evaluate the

patient in terms of a behavioral or psychiatric emergency that may lead to a violent patient reaction:

- How does this patient relate to you? Are your questions answered appropriately? Are the patient's vocabulary and expressions what you would expect under the circumstances?
- Is the patient withdrawn or detached? Is the patient hostile or friendly?
- Does the patient understand why you are there?
- How is the patient dressed? Is the dress appropriate for the time of the year and occasion? Are the clothes clean? Dirty?
- Does the patient appear relaxed, stiff, or guarded? Are the patient's movements coordinated? Does the patient make sudden movements? Is the patient hyperactive?
- Are the patient's movements purposeful—for example, in putting their clothes on? Are the actions aimless, such as sitting and rocking back and forth in a chair?
- Has the patient harmed himself or herself? Is there damage to the surroundings?
- Does the patient appear physically rigid, or is there waxy flexibility?

- What are the patient's facial expressions? Are they bland or flat, or are they expressive? Does the patient show joy, fear, or anger to appropriate stimuli? If so, to what degree?

It might not be possible for you to obtain answers to all of these questions. Sometimes a patient who is experiencing a behavioral emergency will not respond at all. In those cases, the patient's facial expressions, pulse and respirations, tears, sweating, and blushing may be significant indicators of emotional state.

Protective Clothing: Preventing Injury

Wearing protective clothing and other appropriate gear is crucial to your personal safety. It is essential that you become familiar with the protective equipment that is available to you, so that you will know which clothing and gear are needed for the job. You should also be able to adapt or change items as the situation and environment change. Remember that protective clothing and gear are safe only when they are in good condition. It is your responsibility to inspect your clothing and gear. Learn to recognize

Words of Wisdom

Determinants of Violence

The following principal determinants of violence, although not intended to be all-inclusive, are of value to the AEMT:

- **Past history.** Has the patient previously exhibited hostile, overly aggressive, or violent behavior? This information should be solicited by EMS personnel at the scene or requested from law enforcement personnel, family, or previous EMS records.
- **Posture.** How is the patient sitting or standing? Does the patient appear to be tense or rigid, or is the patient sitting on the edge of the bed or chair? The observation of increased tension as shown by physical posture is often a warning signal of hostile behavior.
- **Vocal activity.** What is the nature of the patient's speech? Loud, obscene, erratic, and bizarre speech patterns usually indicate emotional distress. The patient who is conversing in quiet, ordered speech is not as likely to strike out against others as is the patient who is yelling and screaming.

- **Physical activity.** Perhaps one of the most demonstrative factors to look for is the motor activity of a person who is undergoing a behavioral crisis. Patients who are pacing, cannot sit still, or are displaying protection of their boundaries of personal space need careful watching. Agitation is a prognostic sign to be observed with great care and scrutiny.

Other factors to take into consideration for potential violence include the following:

- Poor impulse control
- The behavior triad of truancy, fighting, and uncontrollable temper
- Instability of family structure
- Inability to keep a steady job
- Tattoos, such as those with gang identification or statements like "born to kill" or "born to lose"
- Substance abuse
- Functional disorder (If the patient claims to be hearing voices that say to kill, believe it!)
- Depression
- Diagnosed illness such as bipolar disease

how wear and tear can make your equipment unsafe. Be sure to inspect equipment before you use it; ideally, this is done before reaching the scene so care is not delayed.

Clothing that is worn for rescue must be appropriate for the activity and the environmental conditions in which the activity will take place. For example, turnout gear worn for firefighting may be too restrictive for working in a confined space. In every situation involving blood and/or other body fluids, take standard precautions. You must protect yourself and the patient by wearing gloves and eye protection and any additional protective clothing that may be needed.

Words of Wisdom

NFPA 1999, *Standard on Protective Clothing for Emergency Medical Operations*, outlines criteria for single-use and multiuse protective clothing. Prior to the 2008 revision of this standard, the same physical strength criteria were being used for single-use and multiuse garments. With the revision of the standard, criteria are established for barrier protection, breathability, penetration, flammability, and visibility.²⁴

Cold Weather Clothing

When dressing for cold weather, you should wear several layers of clothing. Multiple layers provide much better protection than a single thick cover. You have more flexibility to control your body temperature by adding or removing a layer. Cold weather protection should consist of at least the following three layers:

1. A thin inner layer (sometimes called the transport layer) next to your skin. This layer pulls moisture away from your skin, keeping you dry and warm. Underwear made of polypropylene or polyester material works well.
2. A thermal middle layer of bulkier material for insulation. Wool has been the material of choice for warmth, but newer materials, such as polyester pile, are also commonly used.
3. An outer layer that will resist chilling winds and wet conditions, such as rain, sleet, or snow. The two top layers should have zippers to allow you to vent some body heat if you become too warm.

When choosing clothing to protect yourself from the weather, pay attention to the type of material used. Cotton should be avoided in cold, wet environments. Cotton tends to absorb moisture, causing chilling from wetness. For example, if you wear cotton trousers and walk through wet grass, the cotton soaks up the moisture from the grass. However, cotton is appropriate in warm, dry weather because it absorbs moisture and pulls heat away from the body.

As an outer layer in cold weather, you might consider plastic-coated nylon because it provides good waterproof protection. However, it can also hold in body heat and perspiration. Newer, less airtight materials allow perspiration and some heat to escape while the material retains its water resistance. Avoid flammable or meltable synthetic material anytime there is a possibility of fire.

Turnout Gear

Turnout, or bunker gear is a fire service term for protective clothing designed for use in structural firefighting environments (**FIGURE 2-15**). Turnout

FIGURE 2-15 Turnout, or bunker gear is protective clothing designed for use in structural firefighting.

© Jones & Bartlett Learning. Photographed by Glen E. Ellman.

gear provides some protection by using different layers of fabric or other material to provide protection from the heat of fire, to reduce trauma from impact or cuts, and to keep water away from the body. Like most protective clothing, however, turnout gear adds weight and reduces range of motion to some degree. Also, turnout gear is hard to clean; avoid using it in situations that will likely expose you to a patient's blood or body fluids.

The exterior fabrics provide increased protection from cuts and abrasions. They also act as a barrier to high external temperatures. In cold weather, an insulated thermal inner layer of material that helps to retain body heat is recommended.

Turnout gear or a bunker jacket provides minimal protection from electrical shock, but it does protect you from heat, fire, possible flashover, and flying sparks. The front opening of the jacket should be fastened, and the jacket should be worn with the collar up and closed in front to protect your neck and upper part of the chest. Proper fit is important so that you can move freely.

Safety

ANSI requires that all EMS providers use an approved high-visibility public safety vest while on or near the roadway.²⁵

Gloves

Firefighting gloves provide the best protection from heat, cold, and cuts, but these gloves reduce manual dexterity (**FIGURE 2-16**). In addition, firefighting gloves will not protect you from electrical hazards. In rescue situations, you must be able to use your hands freely to operate rescue tools, provide patient care, and perform other duties. Puncture-proof leather gloves, with latex gloves underneath, will permit free use of your hands with added protection from injury and body fluids.

Helmets

You should wear a helmet any time you are working in a fall zone. A fall zone is an area where you are likely to encounter falling objects. The helmet should provide top and side impact protection (**FIGURE 2-17**). It should also have a secure chin strap. Objects will often fall one after another: If the

FIGURE 2-16 Firefighting gloves protect your hands and wrists from heat, cold, and injury.

© Jones & Bartlett Learning. Photographed by Glen E. Ellman.

FIGURE 2-17 A helmet with top and side impact protection.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

strap is not secure, the first falling object may knock off your helmet. This leaves your head unprotected as the remaining objects fall.

Construction-type helmets are not well suited for rescue situations. They offer minimal impact protection and have inadequate chin straps. Modern fire helmets afford the best thermal and impact protection.

In cold weather, you can lose a significant amount of body heat if you are not wearing a hat or helmet. An insulated hat made from wool or a synthetic material can be pulled down over the face

and the base of the skull to reduce heat loss in extremely cold weather.

In situations that may involve an electrical hazard, you should always wear a helmet with a chin strap and face shield. The shell of the helmet should be made of a certified electrical nonconductor. The chin strap should not stretch, but rather should fasten securely so that the helmet will stay in place if you are knocked down or a power line hits your head. You should also be able to lock the face shield on the helmet; this will protect your face and eyes from power lines and flying sparks. A standard fire turnout helmet should meet all of these needs.

Boots

Boots should be water resistant, well fitting, and flexible so that you can walk long distances comfortably. If you will be working outdoors, you should choose boots that cover and protect your ankles, keeping out stones, debris, and snow. Steel-toed boots are preferred (**FIGURE 2-18**). In cold weather, your boots must also protect you from the cold. Leather is one of the best materials for boots. However, boots made of other materials, such as waterproof, windproof, and breathable fabrics, are also very good. The soles of your boots must provide traction. Lug-type soles may grip well in snow, but they become very slippery when caked with mud.

Properly fitted boots and shoes are extremely important, because a minor annoyance can progress to become a disabling injury. You may develop painful blisters if your feet slip around inside your boots. However, make sure you have enough room to wiggle your toes.

FIGURE 2-18 Boots should cover and protect your ankles, keeping out stones, debris, and snow. Steel-toed boots are preferred.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Boots should be puncture-resistant, protect the toes, and provide foot and ankle support. It may be difficult to obtain a good fit with firefighting boots; shoe inserts or sock layering may be needed for a comfortable fit. Make sure the tops of your boots are sealed off to prevent entry of rain, snow, glass, or other materials. Moisture increases blistering—wool or wicking socks help prevent feet from becoming wet.

Socks will keep your feet warm and provide some cushioning for you as you walk. In cold weather, two pairs of socks are generally preferable to one thick pair. A thin sock next to the foot helps to wick perspiration away to a thicker, outer sock. This tends to keep your feet warmer, drier, and generally more comfortable. When you purchase new shoes or boots, keep these points in mind.

Eye Protection

The human eye is fragile, and permanent loss of sight can occur from even very minor injuries. You need to protect your eyes from blood and other body fluids, foreign objects, plants, insects, and debris from extrication. You may wear eyeglasses with side shields during routine patient care.

In contrast, when tools are being used during extrication, you should wear a face shield or goggles. In these instances, prescription eyeglasses do not provide adequate protection.

In snow or white sand, particularly at higher altitudes, you must also protect your eyes from ultraviolet exposure. Specially designed eyeglasses or goggles can provide this protection. In addition, your eye protection must be adaptable to the weather and the physical demands of the task. It is crucial that you have clear vision at all times.

Ear Protection

Exposure to loud noises for long periods can cause permanent hearing loss. Certain equipment, such as helicopters, some extrication tools, and sirens, produces high levels of noise. Wearing soft foam industrial-type earplugs usually provides adequate protection.

Skin Protection

Your skin needs protection against sunburn while you are working outdoors. Long-term exposure to the sun increases the possibility of skin cancer.

It might be considered an annoyance, but sunburn is a type of thermal burn. In reflective areas such as sand, water, and snow, your risk of sunburn increases. Protect your skin by applying a sunscreen with a minimum sun protection factor (SPF) of 15.

In addition, because of the need for frequent handwashing, your hands may begin cracking, as the natural oils are also washed off your skin during this procedure. Use hand lotion several times per day, both on and off duty. Your skin is a highly effective barrier to pathogens, as long as it has not been breached by the drying effects of frequent washing.

Body Armor

Although you are trained to avoid any situation that may involve violence, scenes are dynamic and a situation that appears safe initially may deteriorate quickly and become dangerous. For this reason, EMS responders sometimes wear ballistic-resistant or stab-resistant armor for personal protection.

Safety

Remember, ballistic protection is not fail-proof and has the potential to provide a sense of false security.

The National Institute of Justice (NIJ) developed a scale for the global minimum for performance requirements and testing methods for personal body armor.²⁶ The resulting scale is known as the NIJ threat level and is found on the product's label. An expiration date can also be found on the product label. There are five general classifications of protection ranging from extremely lightweight and flexible to heavy and bulky (TABLE 2-5).²⁷ The lighter vests do not stop large-caliber bullets, but they offer more flexibility and are preferred by most EMS and law enforcement personnel. Lighter vests are commonly worn under a uniform shirt or jacket.

The larger, heavier vests are worn on the outside of your uniform and may be bulky and difficult to wear in hot temperatures and high humidity. They are also costly and require replacement at various intervals.

Although body armor may protect underlying organs from penetrating injury, the blunt force trauma may still be significant, especially from

TABLE 2-5 National Institute of Justice (NIJ) Threat Levels	
Threat Level	Protection Offered
Type IIA	Higher velocity and mass ammunition. Examples: 9 mm and .40 Smith & Wesson
Type II	High velocity and those that travel up to 1,400 feet/second. Examples: 9 mm and .357 Magnum
Type IIIA	Better protection from jacketed hollow point rounds. Examples: .44 Magnum and high-velocity 9 mm
Type III	Often used in tactical situations. Examples: Protection from rifles and other high-velocity rounds
Type IV	Highest protection level made with heavy ceramic plates. Example: Armor-piercing bullets

Data from: National Institute of Justice.

high-powered gunfire rounds. Vests also offer little or no protection from fragments that occur during an explosion or against stabbing attacks. Body armor may not be practical in all circumstances, but it still offers a measure of protection that is better than nothing at all.

Familiarize yourself with the type of body armor used by your department and remember that scene safety is always your first concern. The body armor is there for additional protection; it does not take the place of surveying the scene and avoiding dangerous conditions. Like all EMS equipment, training should be done while wearing your vest to ensure ease of use in real-life situations.

Stress

EMS is a high-stress job. Many situations will be stressful for everyone involved, including mass-casualty scenes; serious MVCs; excavation cave-ins; house fires; infant and child trauma; amputations; abuse of an infant, child, spouse, or older adult; and death of a coworker or other public safety personnel. Understanding the causes of stress and knowing how to deal with them are crucial to your job performance, health, and interpersonal relationships. To prevent stress from affecting your life

negatively, you need to understand what stress is, what its physiologic effects are, how to minimize these effects, and how to deal with stress on an emotional level.

Stress is the impact of stressors on your physical and mental well-being. Stressors include emotional, physical, and environmental situations or conditions that may cause a variety of physiologic, physical, and psychological responses. The body's response to stress begins with an alarm response, which is followed by a stage of reaction and resistance, and then recovery or, if the stress is prolonged, exhaustion. This three-stage response is referred to as the **general adaptation syndrome**.

Physiologic responses to stress involve the interaction of the endocrine and nervous systems, which result in chemical and physical responses. This is commonly known as the fight-or-flight response. Positive stressors, such as exercise, and negative stressors, such as shift work, long hours, or the frustration of losing a patient, may all result in the same physiologic manifestations:

- Increased respirations and heart rate
- Increased blood pressure
- Dilated venous vessels near the skin surface (causes cool, clammy skin)

- Dilated pupils
- Muscle tension
- Increased blood glucose levels
- Perspiration
- Decreased blood flow to the gastrointestinal tract

Reactions to stress can be categorized as acute, delayed, or cumulative. **Acute stress reactions** occur during a stressful situation. During this stage, you may feel nervous and excited, and your ability to focus increases. If the stress of the situation becomes too great, however, you may experience emotional and physical reactions to stress.

Delayed stress reactions manifest after the stressful event. During the crisis, you are able to focus and function, but after things have calmed down, you may be left with nervous, excited energy that continues to build and becomes a distraction. Learn certain stress-management techniques to improve your chance of effectively managing this kind of delayed stress when it occurs.

Cumulative stress reactions occur when you are exposed to prolonged or excessive stress. After the stressful event is over, are you able to shake off the effects? Inevitably, another stressful situation occurs, and the cycle repeats. Each time, the AEMT

YOU are the Provider

Part 4

You inform the patient that you would like to clean and bandage his wounds in the back of the ambulance where the lighting is better, and he agrees. Once inside of the ambulance, you examine the injuries and find no arterial sources of bleeding. You then cover the wounds with the appropriate dressings. Finding the patient competent to refuse care, you have the patient sign an EMS Refusal of Care form. As the patient exits the ambulance, you notice blood on the bench seat where the patient was sitting, as well as on the door handles.

Recording Time: 12 Minutes

Respirations	18 breaths/min, normal
Pulse	Strong and regular, 80 beats/min
Skin	Warm and dry
Blood pressure	126/82 mm Hg
Oxygen saturation (SpO ₂)	100% on room air
Pupils	PERRLA

6. How would you decontaminate your ambulance?
7. Should the ambulance be decontaminated alongside the road before you depart the scene, or should you wait to decontaminate until your arrival at the station?

finds it harder and harder to recover and becomes more and more exhausted.

Cumulative stress can have physical symptoms such as fatigue, changes in appetite, gastrointestinal problems, or headaches. Stress may cause insomnia or hypersomnia, irritability, inability to concentrate, and hyperactivity or underactivity. In addition, stress may manifest itself in psychological reactions such as fear, dull or nonresponsive behavior, depression, oversensitivity, anger, guilt, irritability, frustration, isolation, inability to concentrate, alcohol or drug abuse, and loss of interest in work or sexual activity. Often, today's fast-paced lifestyles compound these effects by not allowing a person to rest and recover after periods of stress. Prolonged or excessive stress has been proven to be a strong contributor to heart disease, hypertension, cancer, alcoholism, and depression.

Many people are subject to cumulative stress. In the emergency services environment (EMS personnel, police, firefighters), stressors may also be sudden and severe. Some events are unusually stressful or emotional, even by emergency services standards. These acute severe stressors result in the phenomenon referred to as critical incident stress. Events that can trigger critical incident stress include the following:

- Mass-casualty incidents
- Serious injury or traumatic death of a child
- Crashes with injuries, caused by an emergency services provider while responding to or from a call
- Death or serious injury of a coworker in the line of duty

Posttraumatic stress disorder (PTSD) may develop after a person has experienced one or more psychologically distressing events. PTSD is characterized by reexperiencing the event and over-responding to stimuli that recall the event. In PTSD, social and psychological problems resulting from a failure to resolve traumatic stress or grief can result in delayed reactions classified as “delayed stress syndrome.” Stressful events in EMS are sometimes psychologically overwhelming. Some of the symptoms of PTSD include depression, startle reactions, flashback phenomena, and dissociative episodes (such as amnesia of the event).

Supporting patients in emergency situations is stressful both for them and for you. It is crucial that you recognize the signs of stress so that it does not

TABLE 2-6 Warning Signs of Cumulative Stress

Irritability toward coworkers, family, and friends
Inability to concentrate
Difficulty sleeping, increased sleeping, or nightmares
Feelings of sadness, anxiety, guilt, or hopelessness
Indecisiveness
Loss of appetite (gastrointestinal disturbances)
Loss of interest in sexual activities
Isolation
Loss of interest in work
Increased use of alcohol
Recreational drug use
Physical symptoms such as chronic pain (headache, backache)

© Jones & Bartlett Learning.

interfere with your work and your personal life. The signs and symptoms of chronic stress may not be obvious at first, but rather may be subtle and not present continuously (**TABLE 2-6**).

Stress Management

Many methods must be used to manage stress. Some are positive and healthy; others are harmful or destructive. For example, many people take medications, either prescription or over-the-counter agents, to address the symptoms of stress. Although the medications may provide temporary relief, they do not eliminate the root causes of stress or represent ways to manage it effectively.

The term *stress management* refers to the tactics that have been shown to alleviate or eliminate stress reactions. These may involve changing a few habits, changing your attitude, and demonstrating perseverance (**TABLE 2-7**). Ultimately, dealing with stress as an AEMT requires the ability to emotionally distance yourself from the situation, and accept the limits of what you can personally do.

A clue to the best management approach for stress comes from the fact that it is not the event itself but rather the person's reaction to the event that determines how much the stress will tax the body's

TABLE 2-7 Strategies to Manage Stress

Minimize or eliminate stressors.
Change partners to avoid a negative or hostile personality.
Change work hours.
Change the work environment.
Cut back on overtime.
Change your attitude about the stressor.
Talk about your feelings with people you trust.
Seek professional counseling if needed.
Do not obsess over frustrating situations that you are unable to change, such as relapsing alcoholics and nursing home transfers; focus on delivering high-quality care.
Try to adopt a more relaxed, philosophical outlook.
Expand your social support system beyond your coworkers.
Sustain friends and interests outside emergency services.
Minimize the physical response to stress by using a variety of techniques, including: • A deep breath to settle an anger response • Periodic stretching • Slow, deep breathing • Regular physical exercise • Progressive muscle relaxation and/or meditation • Limit intake of caffeine, alcohol, and tobacco use

© Jones & Bartlett Learning.

resources. Remember that stress results from anything that you perceive as a threat to your equilibrium. Stress is an undeniable and unavoidable part of our everyday life. Understanding how it affects you physiologically, physically, and psychologically can help you manage it more successfully.

A process called **critical incident stress management (CISM)** was developed to address acute stress situations and potentially decrease the likelihood that PTSD will develop after such an incident (**FIGURE 2-19**). This process theoretically confronts the responses to critical incidents and defuses them, directing the emergency services responder toward physical and emotional equilibrium. CISM can occur formally, as a debriefing for those who were present at a scene. In such

**FIGURE 2-19** Critical incident stress management is sometimes used to help providers to relieve stress.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

situations, trained CISM teams of peers and mental health professionals may facilitate this debriefing. Additionally, CISM can occur at an ongoing scene in the following circumstances:

- When personnel are assessed for signs and symptoms of distress while resting
- Before reentering the scene
- During a scene demobilization in which personnel are educated about the signs of critical incident stress and given a buffer period to collect themselves before leaving

Defusing sessions are the first to occur. These sessions are held during the event or immediately afterward. The participants informally discuss events that they experienced together. Defusing sessions are designed to educate the participants as to the expectations over the next few days and to give guidance on proper techniques to manage the feelings they may be experiencing. One example is to discourage drinking alcohol during this stressful time.

Debriefing sessions are held within 24 to 72 hours of a major incident. These meetings involve a CISM team consisting of peers and mental health professionals. At the debriefing session, pent-up emotions can be properly expressed. It is more likely you will be ready to express your emotions more freely a few days following the event.

One of the important rules associated with the debriefing session is to not turn it into an operational critique. No one is right. No one is wrong. No one is to blame. Only emotions about the specific event are to be relayed. These debriefing sessions may also have to be repeated in the future.

CISM programs have been established throughout the United States. CISM teams usually can be found via the Internet, by calling telephone directory assistance in your area and asking for CISM, or they can be requested through your employer. An especially helpful organization is the International Critical Incident Stress Foundation (www.icisf.org), which is dedicated to limiting the effects of stress on EMS providers through education and support services.

Burnout

Why should EMS providers start worrying now about something that may (or may not) happen? Burnout needs to be considered now, at an early stage of training, because now is the time for you to start developing attitudes and habits that will help prevent burnout.

The dictionary defines **burnout** as the exhaustion of physical or emotional strength. Burnout, in fact, may be a consequence of chronic, unrelieved stress. Your job, by its very nature, is full of potential stresses. But burnout does not occur solely because of stress. There are more subtle stresses associated with interpersonal relations, pay, prestige, fringe benefits, and other issues. These complaints and stresses are, no doubt, legitimate. Burnout develops because of the way a person reacts to stress.

One person's eustress (beneficial stress, which may lead to greater motivation or alertness) may be another's distress (harmful stress). The reason is that distress is a learned reaction, based on the way a person perceives and interprets the world. In other words, distress is nearly always the result of what a person believes. Here are some beliefs that are common among EMS personnel:

- I have to be perfect all the time.
- My safety depends on being able to anticipate every possible danger.
- I am totally responsible for what happens to patients; if they die, it is wholly my fault.
- If there is something I do not know, people will think less of me.
- A good AEMT never makes mistakes.

These are all false beliefs and can lead to burnout. Prevention and relief of stress among EMS providers begins with the recognition that such beliefs are unrealistic and invalid.

Like many of the conditions you will study in this text in regard to patients, burnout is a type of illness and has its own set of signs and symptoms. These signs and symptoms may be trivial at first, but when ignored the illness grows in nature until it debilitates you. Symptoms of impending burnout include the following:

- Chronic fatigue and irritability
- Cynical, negative attitudes
- Lack of desire to report to work
- Emotional instability (crying easily, flying off the handle without provocation, laughing inappropriately)
- Changes in sleep patterns (insomnia or sleeping more than usual), and waking without feeling refreshed
- Feelings of being overwhelmed or being helpless or hopeless
- Loss of interest in hobbies
- Decreased ability to concentrate
- Declining health: having frequent colds, stomach upsets, and muscle aches and pains (especially headaches or backaches)
- Constant tightness in your muscles
- Overeating, smoking, or abusing drugs or alcohol

Some AEMTs have been in the field for 20 years and show no signs of burnout, reporting to work every day with the same enthusiasm they did as rookies. What is their secret? In general, the ones who do not experience burnout are those who have learned to respect and value themselves. That is not as easy as it sounds. Practically speaking, what does it mean to respect and value yourself? How can you translate that attitude into concrete actions? Some of the steps you can take to protect yourself from burnout are summarized in **TABLE 2-8**. Notably, one of the best ways of dealing with the stress of working as an AEMT is to invest in relationships and activities outside of work that are meaningful to you.

Compassion Fatigue

Sometimes described as “the cost of caring,” **compassion fatigue** is common among those who work in health care and disaster and emergency services. Compassion fatigue, also known as secondary stress disorder, is a disorder characterized by gradual lessening of compassion over time. It differs from PTSD in that PTSD is caused by direct

TABLE 2-8 Guidelines for Preventing Burnout

1. AEMT, heal thyself! Take care of your own health.
 - Get enough rest.
 - Eat a balanced diet.
 - Get regular physical exercise—at least 30 minutes of aerobic activity (walking, running, or swimming) three to four times per week.
 - Do not abuse your body. Smoking, overindulgence in alcohol, taking recreational drugs, or self-prescribing any other drugs are all forms of self-abuse.
2. Give yourself some “me” time every day. Some of the most stress-resistant providers are those who have learned the techniques of meditation and can use them to escape. Try different methods of meditation or relaxation and see which one works best for you.
3. Learn how to relax.
 - Take time for hobbies.
 - Engage in social activities with people not involved in EMS.
 - Leave your job behind when your shift is over.
4. Do not make unreasonable demands on yourself.
 - Forget the idea that you have to be perfect. No one is perfect. If you do the best job you can, that is good enough.
 - You do not have to be right all the time. Accept the fact that now and then you will make a mistake and that the world will not come to an end on account of it.
5. Do not make unreasonable demands on others.
6. Stay in touch with your feelings.
 - Find someone you can talk to. Share the stress.
 - Cry when you need to. There is no shame in being sad sometimes.
7. Learn techniques for shedding stress while on duty. Do not let stress accumulate.
8. Debrief after tough calls.

Abbreviation: AEMT, advanced emergency medical technician

© Jones & Bartlett Learning.

exposure to a traumatic incident or series of traumatic incidents, whereas compassion fatigue is a reaction to caring for others who have experienced trauma. Symptoms of compassion fatigue include the following:

- High absenteeism
- Difficult relationships with colleagues and coworkers
- Inability to work in teams
- Aggressive behavior toward patients
- Strong negative attitudes toward work
- Lack of empathy for patients
- Judgmental attitude toward patients
- Preoccupation with nonwork issues while on duty
- Other symptoms of increased stress

Supporting patients in emergency situations is difficult. It is stressful for them and for you. You

are vulnerable to all the stresses that go with your profession. It is critical that you recognize the signs of compassion fatigue so it does not interfere with your work or life away from work, including your family life. The signs and symptoms are similar to those of cumulative stress (Table 2-6). They may not be obvious at first; rather, they may be subtle and may not be present all of the time.

Peer Support and Suicide Prevention

Like all people, EMS providers are not immune to thoughts of suicide or suicide attempts. Because prolonged stress is a risk factor for suicide, prevention starts with recognizing that you or your colleagues are becoming overwhelmed. Even if you do not identify suicidal tendencies in yourself, you may receive input from colleagues. Do not

disregard what you recognize or what others note to you. A survey of over 4,000 respondents showed that 37% of EMS respondents contemplated suicide and 6.6% attempted it.²⁸ Although the attempt number may seem relatively low, in comparison, the CDC showed levels for the general population to be 3.9% and 0.6%, respectively.²⁹ The study suggests that emergency workers are at higher risk for suicidal thoughts and attempts than nonemergency workers.

A combination of cumulative stress and acute, intense stress can weigh heavily on EMS providers. Although awareness of EMS provider suicide has grown over the years, you should understand and select strategies to deal with stress in a constructive manner. It is important for you to be aware of the signs of stress and burnout in yourself as well as in coworkers. Any suicidal thoughts or attempts must be taken seriously. If you encounter any suicidal ideations or if a colleague expresses such ideations, you should seek help, including professional counseling.

Peer support is a process by which a properly trained member of your department provides confidential support to another member who is experiencing personal, emotional, or work-related problems and acts as a bridge to outside professional services. Many departments provide both CISD programs and peer support programs. Where CISD is especially valuable following stressful incidents that involve multiple members of a department, peer support is more appropriate for assisting individuals and for situations where ongoing follow-through is needed. Both programs provide valuable assistance for dealing with stressful situations.

One advantage of peer support is that it can build on the existing mutual trust and understanding between two members of the same department. Peer support provides a safe and nurturing environment for all affected members. Trained peer counselors understand the unique needs of public safety providers. They are prepared to adjust to the irregular schedules and other logistical challenges of first responders. They understand the importance of confidentiality, and they understand the physical requirements and mental stressors of being a first responder. Peer counselors can respond in a moment of crisis. They can help to direct a member to self-care, or they can help to provide bridges to outside professional help when needed.

Peer support is voluntary. It can be initiated at the request of the member, a concerned coworker, or a supervisor and may follow a potentially traumatic call. People with whom you work may be able to identify warning signs of stress early and reach out to other team members before these signs become significant problems. Peer counselors can follow up with members weeks or months after a troubling event.

Peer support is not limited to work-related problems. Family issues, financial difficulties, stress or anxiety, and substance abuse are all issues that may be helped through a peer support program. Properly trained peer support personnel can be available to the first responder's family members, too.

The effectiveness of peer support relies on confidentiality. This confidentiality is carefully maintained except in cases where there is a risk of harm to the member or to others, or where there is criminal activity. Check with your supervisor to see if a peer support program is available for members of your department.

Words of Wisdom

Some peer support programs use the acronym LOVE to describe the role of the peer counselor:

- L Listen carefully.
- O Offer assistance.
- V Validate through understanding.
- E Encourage the person to never give up and to seek assistance.

Wellness

Wellness is not simply prevention of disease, but rather a state of complete mental, physical, and social well-being. As a health care provider, you should model a lifestyle of health and wellness.

You will be called on to work in less-than-ideal circumstances and situations, which can challenge your ability to maintain your wellness. Anyone can respond to a sudden physical stress for a short time. If stress is prolonged, however, and especially if physical action is not a permitted response, the body can quickly be drained of its reserves. This can leave it depleted of key nutrients, weakened, and more susceptible to illness.

Words of Wisdom

Resilience is the capacity of an individual to cope with and recover from distress. Although some people tend to be more resilient than others, a person's resilience may change. The following practices can help increase resilience:

- Eat a healthy and well-balanced diet.
- Ensure a minimum of 7 to 9 hours of sleep per day.
- Strengthen positive relationships with close family and friends.
- Build relationships with peers and colleagues.
- Incorporate daily stretching, movement, and exercise.
- Build habits of mindfulness and positivity.

Nutrition

Your body's three sources of fuel—carbohydrates, fat, and protein—are consumed in increased quantities during stress, particularly if physical activity is involved. The quickest source of energy is glucose, taken from stored glycogen in the liver. However, this supply will last less than 1 day. Protein, drawn primarily from muscle, is a long-term source of glucose. Tissues can use fat for energy. The body also conserves water during periods of stress. To do so, it retains sodium by exchanging and losing potassium from the kidneys. Other nutrients that are susceptible to depletion are the vitamins and minerals that are not stored by the body in substantial quantities. These include water-soluble B and C vitamins and most minerals.

As an AEMT, you have little control over which stressors you will face on any given day. Consequently, stress in one form or another will be an unavoidable part of your life as an AEMT. Just as you would study for a test, dress properly for a day of snow skiing, or train for a sporting event, so you should physically prepare your body for stress. Physical conditioning and proper nutrition are the two variables over which you have absolute control. Muscles will grow and retain protein only with sufficient activity. Bones will not passively accumulate calcium. In response to the physical stress of exercise, bones will store calcium and become denser and stronger. Regular, well-balanced meals are essential to provide the nutrients that are necessary to keep your body fueled (**FIGURE 2-20**).³⁰

FIGURE 2-20 The US Department of Agriculture's MyPlate icon emphasizes healthy portions of vegetables, fruits, grains, proteins, and dairy.

Courtesy of the USDA Center for Nutrition Policy and Promotion.

Vitamin–mineral preparations that provide a balanced mix of all the nutrients may be necessary to supplement a less than perfectly balanced diet.

To perform efficiently, you must eat nutritious food. Food is the fuel that makes the body run. The physical exertion and stress that are a part of your job require a high-energy output. If you do not have a readily available source of fuel, your performance may be less than optimal. This can be dangerous for you, your partner, and your patient. Therefore, it is important for you to learn about and follow the rules of good nutrition.

In general, you should limit your consumption of sugar, fats, sodium, and alcohol. Candy and soft drinks contain sugar. These foods are quickly absorbed and converted to fuel by the body. But simple sugars also stimulate the body's production of insulin, which reduces blood glucose levels. For some people, eating a lot of sugar can result in lower energy levels.

Complex carbohydrates rank next to simple sugars in their ability to produce energy. Complex carbohydrates such as pasta, rice, and vegetables are among the safest, most reliable sources for long-term energy production (**FIGURE 2-21**). However, some carbohydrates take hours to be converted into usable body fuel.

FIGURE 2-21 Complex carbohydrates are a good source of long-term energy.

© Digital Vision/Getty Images.

Fats are also easily converted to energy, but eating too much fat can lead to obesity, cardiac disease, and other long-term health problems. The proteins in meat, fish, chicken, beans, and cheese take several hours to convert to energy. Consumption of fats should be limited to 10% of calories and should focus on monounsaturated and polyunsaturated fats while avoiding saturated fats or trans fats. It is also important to limit unhealthy cholesterol intake and salt (sodium) intake.

While on the job, you should carry an individual supply of high-energy food to help you maintain your energy levels. Try eating several small meals throughout the day to keep your energy resources at consistent levels, thereby allowing you to function at the optimal level at all times. Remember, overeating may reduce your physical and mental performance. After a large meal, the blood that is needed for the digestive process is not available for other activities.

You must also make sure that you maintain an adequate fluid intake (**FIGURE 2-22**). Hydration is important for proper functioning. Fluids can be easily replenished by drinking any nonalcoholic, non-caffeinated fluid. Water is generally the best fluid available; the body absorbs it faster than any other fluid. Avoid fluids that contain high levels of sugar, as they can slow the rate of fluid absorption by the body. These beverages can also cause abdominal discomfort. One indication of adequate hydration

FIGURE 2-22 Maintain an adequate fluid intake by drinking plenty of water or other nonalcoholic, caffeine-free fluids.

is frequent urination. Infrequent urination or urine that is dark yellow indicates dehydration.

Exercise and Relaxation

A regular program of exercise will enhance the benefits attained through maintaining good nutrition and adequate hydration. When you are in good physical condition, you can handle job stress more effectively. A regular program of exercise will increase your strength and endurance (**FIGURE 2-23**). Exercise should be moderate or vigorous to have good health benefits. To maintain good health, you should engage in at least 30 minutes of physical

activity at least 5 days per week.³¹ You may also want to practice relaxation techniques, meditation, and visual imagery.

Your exercise routine should involve aspects of cardiovascular endurance, muscular strength building, and muscle flexibility. Endurance will ensure that your cardiovascular system is able to provide your muscles and brain with needed oxygen. Strength and flexibility building ensures that the body is able to handle the requirements that you will place on it by lifting patients, performing CPR, and moving heavy equipment. Exercise is crucial to maintaining a healthy body.

Words of Wisdom

If you do not use it, you lose it! Plan your exercise routine ahead of time, and use strategies that make your session convenient.

Avoidance of Tobacco Use or Cessation

In your career as an AEMT, you will routinely see the effects of tobacco use in your patients—and they are quite sobering. The lesson you should learn from them is simple: If you do not use tobacco or vape, do not start. In addition, smoking by AEMTs sets an awful example for the public, especially to people who have breathing disorders such as asthma. Finally, it makes you look and smell like anything but a professional caregiver.

Use of smokeless tobacco (dry or moist snuff) is associated with cancers of the throat, mouth, and pancreas. Vaping has been shown to produce significant negative effects on the cardiovascular and respiratory systems. It has been cited as the cause of death for dozens of users, from a condition termed e-cigarette (or vaping product) use-associated lung injury.

Street Smarts

You must also understand that everyone responds differently to smoke, and some of your patients may be highly sensitive to it. If you smoke right before a call, the smell on your uniform may be enough to cause serious effects in an already sick patient.

If you are a nicotine user who is trying to quit, first understand that this is truly an addiction and quitting may not be easy. When trying to stop using products containing nicotine, several strategies may help, including the following:

- Create a plan that addresses the challenges that may trigger you to smoke, chew, or vape.
- Set a quit date, preferably within 2 weeks of setting your plan.
- Tell friends, family, and coworkers your plan to quit.
- Remove tobacco and vaping products from your home, car, and work, and, where possible, avoid places where they may be present.
- Talk to your doctor about other resources that may be available to help you quit.

Sleep

Good productive sleep is as important as eating well and exercising to maintain good health. Sleep should be regular and uninterrupted. The number of hours is not nearly as important as the quality of sleep. Unfortunately, as an AEMT, you may not have the luxury of sleeping throughout the night.

Working in EMS systems often imposes schedules on AEMTs that conflict with the body's circadian rhythms, or natural timing system. These rhythms are controlled by special areas of the brain, called the suprachiasmatic nuclei, which govern a person's internal clock. Ignoring your circadian rhythms can cause you to experience consistent difficulty with sleep, thought functions, physical coordination, and even social functions. Signs that your sleep pattern is ineffective include the following:

- You fall asleep within seconds of lying down.
- Within an hour or so after an EMS call, you find yourself routinely fatigued. The excitement is over and now your adrenaline rush crashes.
- You are unable to make it through an entire day without severe fatigue.
- You are unable to concentrate on repetitive tasks such as driving or completing paperwork.

Try to determine what your natural rhythms are, and design a schedule that is best for you. Research on circadian rhythms is only beginning to appear in medical journals, suggesting that someday people might be able to alter their internal clock.

The most important point for all AEMTs is this: Do not overlook the need for rest, whatever your rhythms. Impacts of sleep deprivation may become evident when there is an increase of errors and accidents in the workplace and a decrease in production. As the body becomes deprived of sleep, deficits will be noticed in varying tasks that require logical reasoning or complex thought. Mood may also be affected.³²

Actions that you can take to improve your sleep include limiting your caffeine intake and tobacco use. Both agents have stimulating effects that can interrupt sleep. Also limit your alcohol use. Alcohol is a depressant and encourages sleep, but routine or excessive use of alcohol can change your sleep pattern, preventing deep sleep from occurring. Try to create as consistent a sleep cycle as possible. This may require naps. Many EMS providers are able to change their sleep pattern into several sleep episodes throughout the day.

Do not worry if you are unable to get 8 straight hours of sleep. Three sleep episodes of 2 to 3 hours each will provide similar effects. Each sleep episode needs to be more than 1 hour in length to encourage deep sleep.

Finally, do not forget the effects of exercise and sleep. Routine exercise will promote the needed fatigue to slip into a restful sleep.

Disease Prevention

Besides sleep, diet, exercise, hydration, and all the other things that make up a healthy lifestyle, you need to be aware of the hereditary factors that may influence your wellness. Consider what you might know about the health of your immediate family and your ancestors. Alzheimer disease, chemical addiction, cancer, cardiac illness, hypertension, migraine, mental illness, and stroke all feature prominent hereditary factors. The most common of all hereditary health factors are those affecting the risk for heart disease and cancer.

Share this information with your personal physician. Your physician is bound by the same oath of confidentiality that you are. Work with your physician to set up a schedule for health assessments, building them into your routine physical check-ups. Your physician should be your ally in screening for these diseases and in assessing your lifestyle as well as your hereditary factors.

Knowing your hereditary factors will help you adjust your lifestyle to help prevent disease. For example, if diabetes runs in your family, exercise and diet are crucial to your well-being. Maintaining a healthy weight and sustaining a consistent exercise routine will help minimize your risk of developing this disease.

One of the most important ways to prevent disease is quite simple: If you don't already smoke, don't start! If you do, please stop! Not only does this habit fly in the face of everything that EMS stands for, but it also produces many of the worst cardiovascular and lung disasters that you will confront during your career.

Balancing Work, Family, and Health

As an AEMT, you will often be called to assist the sick and injured at all times of the day and night. Unfortunately, there is no rhyme or reason to the timing of illness, injury, or interfacility transfers. Volunteer AEMTs may often be called away from family or friends during social activities. Shift workers may be required to be apart from loved ones for long periods. Even so, you should never let the job interfere excessively with your own needs. Find a balance between work and family: You owe it to yourself and to them. It is important to make sure that you have the time that you need to relax with family and friends.

It is also important to realize that coworkers, family, and friends often may not understand the stress caused by responding to EMS calls. As a result of a "bad call," you might not feel like going out to a movie or attending a family event that has been planned for some time. In these situations, help from a critical incident stress debriefing team or information sessions conducted by the EMS unit's employee assistance program may assist you in resolving these problems.

When possible, rotate your schedule to give yourself time off. If your EMS system allows you to move from station to station, rotate to reduce or vary your call volume. Take vacations to provide for your good health so that you will be able to better respond the next time you are needed.

If at any point you feel that the stress of work is more than you can handle, seek help. You may want to discuss your stress informally with your family

or coworkers. Help from more experienced team members can be invaluable. You may also want to get help from peer counselors or other professionals. Seeking this help does not make you weak in the eyes of others, but rather demonstrates that you are in control of your life.

Substance Abuse

Alcohol Abuse

Acceptable alcohol consumption is often described to be one drink per day for women and two drinks per day for men. Definitions of excessive drinking are shown in **TABLE 2-9**. In most cases, people who drink excessively are not necessarily alcoholics and do not have a diagnosis of alcohol substance use disorder; however, they may still experience adverse effects.

According to the CDC, excessive alcohol use causes approximately 88,000 deaths per year in the United States, with an economic cost of more than \$200 billion per year. Approximately 75% of the total cost of alcohol abuse is attributed to binge drinking.

Some studies have touted the health benefits related to moderate consumption of alcohol, such as improved heart health from drinking red wine. The CDC notes that no one should start drinking or drink more frequently based on potential reported health benefits. Although these benefits may exist, increased alcohol use may adversely affect other body systems, including the cardiovascular, hepatic, immune, and central nervous systems. Excessive alcohol use may also increase the risk of the development of various cancers, including those of the mouth, throat, breast, esophagus, and liver.

TABLE 2-9 Definitions of Excessive Drinking

	Binge Drinking	Heavy Drinking
Men	5 or more drinks during a single occasion	15 or more drinks per week
Women	4 or more drinks during a single occasion	8 or more drinks per week

Words of Wisdom

If the use of drugs or alcohol has occurred within hours before the start of their shift, the ability of EMS personnel to render emergency medical care may be diminished because of mental or physical impairment. If you observe a coworker who appears impaired, it is your responsibility to immediately report to a supervisor. Covering for this type of behavior is not appropriate and has the potential to cause irreversible harm.

Drug Use

Both prescription medications and illegal, or illicit, drugs may be abused or misused. Both are potentially dangerous and may lead to numerous additional health problems. According to the National Institute on Drug Abuse, drug abuse costs the United States more than \$190 billion annually in lost work productivity, health care, and crime.³³

Illicit drug use is both illegal and unhealthy, typically resulting in a snowball effect of bad outcomes. Many EMS agencies drug test their employees. Those who test positive for illegal drugs, or even for prescription drugs when a bona fide medical use cannot be verified by a physician, face suspension and/or dismissal and may lose their certification. Therefore, avoid all illegal drugs; take only those drugs prescribed for you personally by a physician, and take them only as directed. In certain cases, even a drug prescribed by a physician should not be taken if the AEMT plans to work. The benefits of the drug versus the chance that its effects could impair the performance and safety of the AEMT, the crew, the patient, and the public must always be considered. If any type of restricted, scheduled, or narcotic drug is prescribed (usually for use while you are off duty), be sure to notify your employer of the situation.

Safety

Substance abuse does not just reduce EMS personnel's ability to provide safe and effective patient care, it also compromises the safety of that responder and other members of the team. Ignoring a substance abuse problem puts you and those you work with at increased risk.

Workplace Issues

As our society continues to grow more culturally diverse, some groups that may have been satisfied in the past to accept and participate in American cultural traditions may seek instead to assert, preserve, and nurture their differences. As our society grows more culturally diverse, so do EMS workplaces. You are required to provide an equal standard of care to all patients. You also need to be able to work efficiently and effectively with other health care professionals from a variety of different backgrounds.

Diversity on the Job

Each person is different, and you should communicate with coworkers and patients in a way that is sensitive to everyone's needs. Look at cultural diversity as a resource and make the most of the differences among people in EMS, thereby enabling them to provide optimal patient care. It is possible to build the strength of your workgroup through diversity. Be respectful toward others who differ from you in terms of culture, race/ethnicity, religion, and other bases, and be sensitive to their needs when communicating with them.

Words of Wisdom

When you are working with patients or calling the hospital on the radio, other AEMTs may be sensitive to how you treat patients from their cultural group. Therefore, when referring to patients, you should use the appropriate terminology. Avoid using terms such as *crippled*, *deformed*, *deaf*, *dumb*, *crazy*, and *retarded* when referring to patients. Instead, use the term *disabled*, and describe the specific disability.

For many years, EMS and public safety services in many regions of the United States have been dominated by white men. This trend is falling by the wayside, as more women and minorities begin working in public safety. The proactive AEMT understands the benefits of using cultural diversity to improve patient care and expects to work alongside workers with different backgrounds and to accept their differences.

Cultural diversity in EMS allows you to enjoy the benefits from fully realizing the skills of a broad range of people. When you accept coworkers as

individuals, the need to fit them into rigid roles is eliminated. To be more sensitive to cultural diversity issues, you must first be aware of your own cultural background. Ask yourself, "What are my own issues relative to race, color, religion, and ethnicity?" Because culture is not restricted to different nationalities, you should also consider age, disability, handicap, gender/gender identity, sexual orientation, marital status, work experience, and education.

Remember that your patients and their families will likely span a wide range of cultures. Although it is unrealistic to become a cross-cultural expert with knowledge about all ethnicities, you should learn how to relate and communicate effectively with coworkers and patients from various backgrounds. Even the perception of discrimination can weaken morale and motivation and negatively affect the goal of EMS; be aware of how your words or actions could be interpreted by a person from another culture.

As a health care professional, you should try to be a role model for new AEMTs by showing them the value of diversity. If you are working with a coworker or patient from a particular cultural group, be careful about any opinion you may have formed about that group. Do not assume that there is a language barrier, and do not seem patronizing by saying, "Some of my best friends are . . ." Recognize that there are legitimate differences in how various cultures respond to stress. For example, you should be prepared to accept that people of different cultures might respond differently to the death of a loved one.

You might want to consider taking multilingual training classes. This training not only will be useful in communicating with your coworkers, but also will improve your ability to communicate with your patients and will help you become accustomed to the culture of the people who are using the language.

Sexual Harassment

Sexual harassment is any unwelcome sexual advance, unwelcome request for sexual favors, or other unwelcome verbal or physical conduct of a sexual nature when submitting is a condition of employment, submitting or rejecting is a basis for an employment decision, or such conduct substantially interferes with performance and/or creates a

hostile or offensive work environment.³⁴ Remember that even an overheard conversation can be construed as sexual harassment.

There are two types of sexual harassment: *quid pro quo* (the harasser requests sexual favors in exchange for something else, such as a promotion) and hostile work environment (jokes, touching, leering, requests for a date, talking about body parts). Sexual harassment complaints include complaints of a hostile work environment. Remember, it does not matter what the intent or who the harasser was; what matters are the other person's perceptions and what impact the behavior had on that person. For many years, it was not uncommon to walk into a fire station and see sexually suggestive posters, calendars, or cartoons and to hear sexual jokes or comments. This situation is changing because it is not acceptable professional practice.

Because AEMTs and other public safety professionals depend on each other for their own safety, it is especially important to try to develop nonadversarial relationships with coworkers. Most EMS facilities and fire stations make arrangements for different bunkrooms for men and women. If this is not the case at your facility, you should discuss this with your supervisor and talk openly with coworkers of the opposite gender to allow for their privacy.

If you are concerned about a specific behavior, it may be helpful to ask yourself these questions: "Would I do or say this in front of my spouse, significant other, or parents?" "Would I want my family members to be exposed to this behavior?" "Would I want my behavior videotaped and shown on the evening news?"

If you have been harassed, you should report it to your supervisor immediately according to your local policy and procedure. Keep factual documentation of what happened and what was said. You should confront the harasser only if you feel comfortable doing so. If you are asked for a date, say, "I'm not interested." If remarks or touching offends you, say, "Please don't say/do that to me; it offends me."

If your employer's complaint mechanism does not resolve your grievance regarding sexual harassment, then you may need to file a complaint with the Equal Employment Opportunity Commission (EEOC). When investigating allegations of sexual harassment, EEOC looks at the whole record: the circumstances, such as the nature of the sexual

advances, and the context in which the alleged incidents occurred. Its decision about the sexual harassment allegations is then made from those facts, on a case-by-case basis.³⁴

The best way to deal with sexual harassment is to prevent it from occurring at all. Each agency must develop—and then enforce—a policy on sexual harassment. Training on this issue should also be provided, if necessary. In addition to hurting morale and potentially leading to ineffective performance by employees, sexual harassment can have dire consequences for the EMS system as a whole: If it must defend itself in a sexual harassment case, it runs the risk of a large financial loss if found culpable.

Death and Dying

Today, death is likely to occur somewhere other than the home—such as in the hospital, in a convalescent home, at work, or on the highway, and death is likely to occur quite suddenly or after a prolonged terminal illness. Life-support systems and impersonal care remove the whole experience of death from most people's awareness. The mobility of families also makes it less likely that there will be extended family support when death occurs. For these reasons, we are less familiar with death than our ancestors were.

No matter what the frequency of response to emergency calls, death is something that every AEMT will face. During these situations, you must exercise extreme caution in your words and your actions. For some AEMTs, it may be an infrequent occurrence. Others, especially in urban settings, may see death many times in responding to MVCs, drug overdoses, suicides, or homicides. Some EMS personnel will deal with the mass-casualty incident

Words of Wisdom

In the event of a death, you must handle the body with respect and dignity. The body must be exposed as little as possible. Learn your local regulations and protocols about moving the body or changing its position, especially if you are at a possible crime scene. Even in these situations, CPR and appropriate treatment must be given unless there are obvious signs of death.

of an airplane crash or a hazardous materials accident. In all of these cases, coming to grips with your thoughts, understandings, and adjustment to death is not only important personally, but also a function of providing emergency medical care.

The Grieving Process

The death of a human being is one of the most difficult events for another human being to accept. If the survivor is a relative or close friend of the deceased, it is even more difficult. Emotional responses to the loss of a loved one or friend are appropriate and should be expected. In fact, it is expected that you will feel emotional about the death of a patient. Feelings and emotions are part of the grieving process. All of us experience these feelings after a stressful situation that causes us personal pain.

In 1969, Elisabeth Kübler-Ross published *On Death and Dying*,³⁵ revealing that people go through several stages of grief:

1. **Denial.** Refusal to accept diagnosis or care, unrealistic demands for miracles, or persistent failure to understand why there is no improvement.
2. **Anger and hostility.** Projection of bad news onto the environment and commonly in all directions, at times almost at random. The person lashes out. Someone must be blamed, and those who are responsible must be punished. This is typically an unpleasant phase.
3. **Bargaining.** An attempt to secure a prize for good behavior or a promise to change lifestyle. "I promise to be a 'perfect patient' if only I can live until 'x' event."
4. **Depression.** Open expression of grief, internalized anger, hopelessness, or the desire to die. It sometimes involves suicidal threats, complete withdrawal, or giving up long before the illness seems terminal. The patient is usually silent.
5. **Acceptance.** The simple "yes." Acceptance grows out of a person's conviction that all has been done and the person is ready to die. Although the acceptance phase is usually the most peaceful for the patient, it is often the most traumatic for the family.

These stages may follow each other in sequence or occur simultaneously. A person may jump back and forth between stages or may not experience

some stages at all. The stages may last for different spans of time. Family members may experience similar phases.

Working With Family Members

Although you must treat all patients with respect and dignity, use special care with dying patients and their families (**TABLE 2-10**). Be concerned about their privacy and their wishes, and let them know that you take their concerns seriously. However, it is best to be honest with patients and their families; do not give them false hope.

When working with the family of a patient who has died, ask whether there is anything you can do that will be of help, such as calling a relative or a religious advisor. Provide gentle and caring support. Reinforcing the reality of the situation is important. This can be accomplished by merely saying to a grieving person, "I am so sorry for your loss." It is not important that you have a well-rehearsed script, as it is not likely that your exact words or consolations will be remembered. Rather, the important thing is to be honest and sincere.

Some statements of consolation may sound trite, and some suggest a kind of silver lining behind

TABLE 2-10 Responding to Grief

Do Not Say . . .	Try Instead . . .
Give it time. Things will get better.	I'm sorry for your loss.
You should not question God's will.	It is okay to be angry.
You have to get on with your life.	It must be hard to accept.
You have to keep going.	That must be painful for you.
You can always have another child.	Tell me how you are feeling.
You're not the only one who suffers.	If you want to cry, it's okay.
Life goes on.	People really cared for . . .
I know how you feel.	I can only imagine how terrible this must be for you.

the clouds. Although they may be intended to make the person feel better about a situation, they also can be viewed as an attempt to diminish the person's grief. The grieving person needs to grieve. Statements like these can also indicate our inability to comprehend the profound sadness of grief because we have not experienced that kind of loss.

All people will experience grief and respond to it in their own way. Attempts to take grief away too quickly are not good. If you do not know how the person really feels, you should not say that you do. People may be offended by responses that give advice or explanations about the death. Statements such as "Oh, you shouldn't feel that way" are judgmental. If you judge what the grieving person is feeling, it is likely that the person will stop talking with you. There is no right or wrong way to grieve.

Remember that anger is a stage of grieving. Patients or family members may express rage, anger, and despair, and their anger may be directed at you. This anger seems irrational to everyone but the person grieving. A professional attitude is a necessity, and you must not take this anger as a personal attack. The patient's or family's concerns will usually be relieved by your calm, efficient manner.

Statements and comments that suggest action on your part are generally helpful. These statements imply a sense of understanding; they focus on the grieving person's feelings. It is not necessary to go into an extensive discussion. You may say, "I am so sorry. I just want you to know that I am thinking about you." What people really appreciate is somebody who will listen to them. Simply ask, "Would you like to talk about how or what you are feeling?" Then accept the response.

Words of Wisdom

Be compassionate, but remember that patient care always takes precedence in emergency situations. It would be inappropriate to prioritize a screaming, frightened child with minor injuries over another patient who has life-threatening injuries.

Working With the Patient

Although the event (death) has not yet happened, the dying patient knows that it will happen. The patient has no control over this process. The patient

TABLE 2-11 Concerns of the Dying, Critically Ill, or Injured Patient

Anxiety
Pain and fear
Anger and hostility
Depression
Dependency
Guilt
Mental health problems
Receiving unrelated bad news

© Jones & Bartlett Learning.

will die whether ready or not. Furthermore, being ready to die does not mean that the patient will be happy about dying. You may encounter situations in which the patient is close to death, and you may need to provide reassurance and emotional care.

People who are in the process of dying as a result of trauma, an acute medical condition, or a terminal disease will feel threatened. That threat may be related to their concern about survival. These concerns may involve feelings of helplessness, disability, pain, and separation (**TABLE 2-11**).

Words of Wisdom

Many factors influence how a patient reacts to the stress of an emergency incident. Among these factors are the following:

- Personality
- Socioeconomic background
- Fear of health care personnel
- Alcohol or substance abuse
- History of chronic disease
- Mental disorders
- Reaction to medication
- Age
- Nutritional status
- Feelings of guilt
- Past experience with illness or injury

Do not make light of a patient's pain and fear. Instead, you might say, "I'm sure you are really scared right now, but you should know that I am doing everything I can to help you." Making a

connection with your patient through eye contact and the squeeze of a hand can often do more to allay fear than the most eloquent words. The following sections discuss some of the responses you may receive from critical patients.

Anxiety

Anxiety is a response to the anticipation of danger. The source of the anxiety is often unknown, but in the case of seriously injured or ill patients, the source is usually recognizable. What may increase the anxiety are the unknowns of the current situation. Patients may ask the following:

- What will happen to me?
- What are you doing?
- Will I make it?
- What will my disabilities be?

Patients who are anxious may have the following signs and symptoms:

- Emotionally upset
- Sweaty and cool skin (diaphoretic)
- Rapid breathing (hyperventilating)
- Fast pulse (tachycardic)
- Restlessness
- Tension
- Fear
- Shakiness (tremulous)

For the anxious patient, time seems to be extended: Seconds can seem like minutes and minutes can seem like hours. It is your job to do everything you can to reduce the patient's anxiety and help the patient cope and minimize the physiologic harm caused by anxiety.

Pain and Fear

Pain and fear are interrelated. Pain often is associated with illness or trauma. Fear is generally thought of in relation to the oncoming pain and the outcome of the damage. It is often helpful to encourage patients to express their pains and fears; this expression begins the process of adjusting to the pain and accepting the emergency medical care that may be necessary. Some people have difficulty openly admitting their fear. The fear may be expressed as bad dreams, withdrawal, tension, restlessness, "butterflies" in the stomach, or nervousness. In some cases, it may be expressed as anger.

Anger and Hostility

Anger may be expressed by very demanding and complaining behavior. Often this may be related to the fear and anxiety caused by the emergency itself or by the medical care that is being given. Sometimes the fear is so acute that the patient may want to express anger toward you or others but is unable to do so because of the dependency factor. If you find that you are the target of the patient's anger, make sure that you are safe; do not take the anger or insults personally. Be tolerant, and do not become defensive.

Anger may also be expressed physically, and you may be the target of the displaced aggression. If the patient or a relative becomes so emotionally upset that you are physically assaulted or you believe that this could happen, retreat from the situation. Such hostility must be contained. If emergency medical care is not possible under these circumstances, law enforcement intervention is required.

Depression

Depression is a natural physiologic and psychological response to illness, especially if the illness is prolonged, debilitating, or terminal. Whether the depression is a temporary sadness or clinical depression that has a long history, there is, of course, little you can do to alleviate the pain of depression during the brief time the patient is being treated and transported. The best you can do in treating and transporting a patient experiencing depression is to be compassionate, supportive, and nonjudgmental.

Dependency

Dependency usually takes longer to develop than is possible with the very brief relationships developed in EMS. However, when medical care is given to any individual, a sense of dependency may develop. People who are placed in this position may feel helpless and become resentful. The resentfulness may arouse feelings of inferiority, shame, or weakness. Make every attempt to remain supportive and compassionate.

Guilt

Many patients who are dying, their families, or the caregivers of the patients may feel guilty about what has happened. Occasionally family members

and long-term caregivers may feel a degree of relief when an extended illness is finally over. That relief may later turn into guilt. Most of the time, however, no one can explain these feelings. The magnitude of the guilt may be great. Sometimes, feelings of guilt can result in a delay in seeking emergency medical care. Again, understanding the complex emotions that often surface during times of emergency may help you cope with some of the intense behavior you will encounter as an AEMT.

Mental Health Problems

Mental health problems such as disorientation, confusion, or delusions may develop in the dying patient. In these instances, the patient may display behavior inconsistent with normal patterns of thinking, feeling, or acting. Common characteristics of such behavior may include the following:

- Loss of contact with reality
- Distortion of perception
- Regression
- Diminished control of basic impulses and desires
- Abnormal mental content, including delusions and hallucinations

In some long-term situations, generalized personality deterioration may occur. See Chapter 24, *Psychiatric Emergencies*, for a discussion on mental health.

Receiving Unrelated Bad News

A patient who is in critical condition or is dying may not want to hear unrelated bad news, such as a message about the death of a close relative or friend. Such news may depress the patient or cause the patient to give up hope.

Dealing With the Death of a Child

The death of a child is a tragic and dreaded event. It is not unusual to think about the fact that a dead or dying child is missing out on a lot more of life. In our society, we assume that only older people are supposed to die. Children die less frequently now than they did in earlier times, so most people are unprepared for what they will feel when a child dies. You may think about your own children and those whom you know: nephews, nieces, grandchildren, and children of close friends. And you

may think, “Why should this child, who is only 5 years old, die?”

Answering the difficult questions about your own mortality will be of help when dealing with the death of a child. Even so, the death of a child will not be an easy subject to discuss. This will be especially true for the family. As an AEMT involved in a call that involves the death of a child, you will also likely experience stress.

One of your responsibilities is to help the family through the initial period after the death. Until more definitive and professional help can be available, you may be in the best position to help family members begin to cope with their loss. How family members deal with the death of a child will affect their stability and endurance. You can help family members through the initial period of grief and alert them to the follow-up counseling and support services that are available.

If the child is dead, acknowledging the fact of the death is important. This should be done in a private place, even if that is inside an ambulance. Often, the parents cannot believe that the death is real, even if they have been preparing for it, as in the case of a child with a terminal illness. Reactions vary, but shock, disbelief, and denial are common. Some parents show little emotion at the initial news.

If possible and appropriate, find a place where the mother and father can hold the child. This is important in the parents’ grieving process; it helps to lessen the sense of disbelief and makes the death real. Even if the parents do not ask, you should tell them that they can see the child. Your decision in permitting the parents to see the child may need some discretion. For example, in the case of a traumatic death in which there is significant disfigurement, that decision might have to be delayed. The delay may involve having support services available or contacting the family physician or others who can help the parents through this difficult situation. This may involve preparing the parents for what they will see and the changes brought on by rigor mortis or asphyxiation, for example.

Sometimes you do not need to say much. Alternatively, you may choose to express your own sorrow. Do not overload grieving parents with a lot of information; at this point, they cannot handle it. Nonverbal communication, such as holding a hand or touching a shoulder, may also be valuable. Let the family’s actions be your guide regarding what is

appropriate. It is important to encourage parents to talk about their feelings.

Caring for Critically Ill and Injured Patients

When you are caring for a critically ill or injured patient, the patient needs to know who you are and what you are doing. Let these patients know that you are attending to their immediate needs and that these are your primary concerns at that particular moment (**FIGURE 2-24**). As soon as possible, explain to the patient what is going on. Confusion, anxiety, and other feelings of helplessness will be decreased if you keep the patient consistently informed. For example, patients may be concerned about the safety or well-being of others who are involved in the accident and about the damage or loss of personal property. Your responses must be discreet and diplomatic, giving reassurance when appropriate. If a loved one has been killed or critically injured, you should wait, if possible, until clergy or emergency department staff can inform the patient. They can then provide the psychological support the patient needs.

Some patients, especially children and older adults, may be terrified or feel rejected when separated from family members by the uniformed

EMS provider team. Other patients may not want family members to share their stress, see their injury, or witness their pain. It is usually best if parents go with their children and relatives accompany older patients.

Religious customs or needs of the patient must also be respected. Some people will cling to religious medals or charms, especially if any attempt is made to remove them. Others will express a strong desire for religious counsel, baptism, or last rites if death is near. You must try to accommodate these requests if it is practical. Some people have religious convictions that strongly oppose the use of drugs and blood products. If you obtain such information, it is imperative that you report it to the personnel who will be responsible for the next level of care. The following sections provide effective techniques for communicating with a critical patient.

Avoid Sad and Grim Comments

AEMTs, other safety personnel, family, and bystanders must avoid grim comments about a patient's condition. Remarks such as "This is a bad one" or "The leg is badly damaged, and I think he will lose it," are inappropriate. These remarks may upset or increase anxiety in the patient and compromise possible recovery outcomes. This is especially true for the patient who may be able to hear but not respond.

Orient the Patient

You should expect a patient to be disoriented in an emergency situation. The aura of the emergency situation—lights, sirens, smells, and strangers—is intense. The effect of injuries or acute illness may cause patients to be confused or unsettled. It is important to orient patients to their surroundings (**FIGURE 2-25**). Use brief, concise statements, such as "Mr. Smith, you have had an accident, and I am now splinting your arm. I am John Foxworth of the New Britain EMS; I will be caring for you."

Be Honest

When approaching any patient, you must determine the patient's ability to understand and accept. You should be honest without further shocking the patient or giving information that is unnecessary or that may not be understood. Simply explain what

FIGURE 2-24 Let the patient know immediately that you are there to help.

© Jessica Rinaldi/Boston Globe/Getty Images.

FIGURE 2-25 The aura of an emergency situation can be confusing and frightening to the patient. Make sure you explain to the patient what has happened and what you are doing.

© Tom Carter/age fotostock.

you are doing and allow the patient to be part of the care being given; this can relieve feelings of helplessness and some of the fear.

Initial Refusal of Care

On occasion, patients may refuse emergency medical care, insisting that you do nothing and leave them alone. In these cases, it is important to impress on the patient the seriousness of the condition without causing undue alarm. Saying, “Everything will be okay,” when it is obvious that it will not be, makes you appear dishonest. Generally, seriously ill or injured patients know that they are in trouble; however, many people refuse care because of their inability to pay the medical expenses. It is imperative to stress to patients that their inability to pay should in no way have a bearing on whether they seek care. If there is a need, EMS should be called and the patient will receive appropriate care regardless of the person’s financial situation.

Allow for Hope

In trauma and acute medical conditions, patients may ask you whether they are going to die. You may feel at a loss for words. You may also know, on the basis of experience or in view of the seriousness of the present situation, that the prognosis is poor. Even so, it is not your responsibility to tell patients that they are dying. Statements such as “I don’t know when you are going to die; let’s deal with the

current problem,” or “I’m not going to give up on you, so don’t give up on yourself,” are helpful. These statements transmit a sense of trust and hope, and they let patients know that you are doing everything possible to save their life. If there is the slightest chance of hope remaining, you want that message transmitted in your attitude and in the statements you make to the patient.

Locate and Notify Family Members

Many patients will be concerned and ask you to notify their family or others close to them. The patient may or may not be able to assist you in doing this. You should ensure that an appropriate and responsible person makes an effort to locate the desired people. Assuring the patient that someone is going to do this is a significant part of the patient’s care because it will help to calm the patient.

Street Smarts

When you are transporting an older adult who lives with a spouse or other older relative or friend, try to transport that person along with the patient if time permits. Many older adults cannot drive.

Injured and Critically Ill Children

Children who are critically ill or injured should be cared for as any patient would be, insofar as an assessment of the ABCDEs (airway, breathing, circulation, disability, and exposure) and immediate life threats are concerned. Due regard should be given to variations in height, weight, and size in providing emergency medical care to pediatric patients.

When children are seriously ill or injured, family members and other people at the scene may become frantic. You need to remain calm and confident in your skills—this may be all that is needed to provide reassurance to everyone at the scene. Children will often respond better to a person who is calm, even if their illness or injury is significant. Because of the increased excitement and extraordinary nature of the emergency scene for a child, it is important that a relative or responsible adult accompany the child to relieve anxiety and assist in care as appropriate.

Uncertain Situations

There will be times when you are unsure whether a true medical emergency exists. If you are unsure, contact medical control about the need to transport. If you cannot reach medical control, it is always best to err on the side of caution and transport the patient. For ethical and medicolegal reasons, a physician must examine all patients who are transported and determine the degree of medical need.

Many minor signs or symptoms may be early indicators of severe illness or injury. Symptoms of many illnesses can be similar to those of substance abuse, hysteria, or other conditions. You must accept the patient's complaints and provide appropriate care until you are able to transfer care of the patient to a higher level (such as a paramedic, nurse, or physician). Your local protocols will direct your actions in these situations. When in doubt, err on the side of caution, and acquire the patient's consent and transport to the medical facility.

YOU are the Provider SUMMARY

1. Do you have a duty to provide care to this patient?

Yes, you have a duty to provide care to this patient. Because this crash occurred in your presence, and you are available for service, you have the responsibility to evaluate the patient and provide any needed care and treatment. Depending on jurisdictional requirements, you may or may not have to notify the local ambulance service and have its personnel respond as well. Regardless of this patient's HIV status, he has a right to receive appropriate medical care.

2. What is the minimal amount of PPE you would want to have on prior to exiting the ambulance?

At a minimum, both you and your partner should be wearing some type of American National Standards Institute (ANSI) II high-visibility compliance clothing (vest, jacket), gloves, mask, eye protection, safety-toed boots, and, if applicable to your jurisdiction, fire-fighting-type turnout gear.

3. What is the minimal amount of PPE you would want to have on prior to initiating care?

As with any patient, the appropriate PPE should be based on the anticipated exposures. With the amount of blood present, you should have on eye protection, gloves, and a face shield and gown. The patient's HIV status does not require any additional PPE other than standard precautions.

4. Does the fire department need to be informed of the patient's HIV-positive status?

The patient has a right to have his health status remain private. Because of Health Insurance Portability and Accountability Act (HIPAA) regulations, the

firefighters would need to be informed of his status only if they might come in contact with potentially biohazardous substances.

5. Does this patient have the right to refuse care?

As with all patients, as long as he is competent to refuse care (not under the influence of intoxicating substances) and understands the risks and consequences of refusing care, this patient has every right to refuse care.

6. How would you decontaminate your ambulance?

The substance that should be used to decontaminate your ambulance will vary depending on departmental policies, but you can use a bleach and water solution at a dilution of 1:10 to clean the unit. The solution you mix should not have a strong odor of bleach if mixed correctly. A hospital-approved disinfectant that is effective against *Mycobacterium tuberculosis* can also be used. Use the cleaning solution in a bucket or pistol-handled spray container, making sure to thoroughly clean all surfaces, especially common areas, such as door handles.

7. Should the ambulance be decontaminated alongside the road before you depart the scene, or should you wait to decontaminate until your arrival at the station?

The location where you clean your ambulance will again depend on local policies. It is recommended that you clean the ambulance as soon as practical on contamination. Regardless, the ambulance should be placed out of service until it can be completely decontaminated.

YOU are the Provider **SUMMARY** *continued***EMS Patient Care Report (PCR)**

Date: 1-12-21	Incident No.: 20107913557	Nature of Call: Witnessed MVC	Location: I-29 SB MM214		
Dispatched: 1233	En Route: 1233	At Scene: 1233	Transport:	At Hospital:	In Service: 1257

Patient Information

Age: 54
Sex: M
Weight (in kg [lb]): 101 kg (222 lb)

Allergies: NSAIDs
Medications: Enfuvirtide
Past Medical History: HIV+
Chief Complaint: Multiple lacerations

Narrative

While returning from Altru Hospital, Medic 6284 witnessed a single vehicle rollover MVC on I-29. Vehicle appeared to be traveling at approximately 55 mph when it swerved, lost control, and rolled 3-4 times. Patient was restrained, no airbag deployment, passenger compartment intact. Patient presents with copious amounts of blood on his arms, states he is HIV+. Proper PPE in place. Manual immobilization to cervical spine established. Patient denies any loss of consciousness or head, neck, or back pain. He states his only complaint is arm pain from the lacerations. Patient further refuses to be secured to long backboard, and only wishes to be treated and not transported. Assisted patient to back of ambulance, where wounds were examined. No arterial bleeding noted. Bleeding controlled with pressure and dressings applied. Advised patient of need to be evaluated in emergency department for possible sutures. Also advised patient of risks and consequences of refusing EMS, up to and including death. Patient verbalized understanding of refusing EMS, and appeared competent to refuse. Appropriate forms signed. Patient left in care of law enforcement on scene. Medic 6284 returned to service.

End of report

Prep Kit

Ready for Review

- As an AEMT, you will arrive at scenes where potential danger to you is easily apparent. Every patient encounter should be considered potentially dangerous. Therefore, it is essential that you take all available precautions to minimize exposure and risk. Potential risks include scene hazards and infectious and communicable diseases.
- A communicable disease is any disease that can be spread from person to person or from animal to person.
- Infectious diseases can be transmitted by contact (direct or indirect); they are spread by airborne, foodborne, or vector-borne means.
- Even if you are exposed to an infectious disease, your risk of becoming ill is low. Whether or not an acute infection occurs depends on several factors, including the amount and type of infectious organism and your resistance to that infection.
- You can take several steps to protect yourself against exposure to infectious diseases, including remaining up-to-date with recommended vaccinations, following standard precautions at all times, and handling all needles and other sharp objects with great care.
- Because it is often impossible to tell which patients have infectious diseases, you should avoid direct contact with the blood and body fluids of all patients.
- Standard precautions are protective measures designed to prevent health care workers from coming in contact with germs carried by patients. One extremely effective step is properly washing your hands. You must also use the proper PPE for the situation, including gloves, gowns, eye protection, masks, and possibly other specialized equipment.
- Keep immunizations up to date. Recommended immunizations include tetanus and diphtheria boosters (every 10 years); MMR vaccine; influenza vaccine (yearly); hepatitis B vaccine; and varicella (chickenpox) vaccine if you have not had chickenpox. You should also have a skin test for tuberculosis before you begin working as an AEMT and ensure that you receive appropriate regular testing as dictated by your employer's health department.
- Infection control should be an important part of your daily routine. Be sure to follow the proper steps when dealing with potential exposure situations.
- You should know what to do if you are exposed to an airborne or bloodborne disease. Your department's designated officer will be able to help you follow the protocol set up in your area.
- If you think you may have been exposed to an infectious disease, see your physician (or your employer's designated physician) immediately.
- Cleaning and disinfecting the ambulance is an important part of protecting yourself and patients. Use cleaning solutions that are appropriate for the equipment category.
- During your career as an AEMT, you will be exposed to many hazards. In a life-threatening situation, you should be properly protected, or you must avoid the situation altogether.
- Scene hazards may include traffic hazards, unstable vehicles, potential exposure to hazardous materials, electricity, and fire. Your safety is the most important consideration. Never approach a scene without first observing it from a safe distance.
- Hazards associated with a vehicle crash are some of the most unstable and lethal. Be very conscious about the flow of traffic. When approaching damaged vehicles, look for signs of fluid leakage. Look for signs of vehicle instability. Other rescuers may need to work at the scene before you can safely provide patient care.
- If a hazardous material may be present, do not begin caring for patients until they have been moved away from the scene by the hazardous

materials team and properly decontaminated, or until the scene has been made safe for you to enter.

- Electrical shock can be produced by power lines or by lightning. If you encounter a downed power line, do not touch it. Mark off a danger zone around the downed lines and contact the power company. If a lightning strike is possible, move immediately to the lowest area possible. If you are in an open area, position yourself in a low crouch. If possible, get inside a vehicle or your unit, as it may provide some measure of protection.
- Five common hazards in a fire include smoke, oxygen deficiency, high ambient temperatures, toxic gases, and building collapse. You must be trained in the use of appropriate protective equipment and have it available at all fire scenes. Follow the instructions of the incident commander while on scene.
- Wearing protective clothing and other appropriate gear is crucial to your personal safety. Protective clothing and gear must be in good condition, and may include cold weather clothing, turnout gear, firefighting gloves, helmets, boots, eye protection, ear protection, skin protection, and possibly body armor. A high-visibility public safety vest must be worn while on or near a roadway.
- Violent situations such as civil disturbances, domestic disputes, and crime scenes can create many hazards for EMS personnel. Whenever you are in doubt about your safety, do not put yourself at risk. If you see the potential for violence when you are sizing up the scene, call for the appropriate resources. Rely on the advice of law enforcement.
- Stress reactions can be acute, delayed, or cumulative. PTSD is a syndrome with onset following a traumatic, usually life-threatening event. CISM is a process developed to address acute stress situations. AEMTs may also seek help through an employee assistance program.
- When signs of stress such as fatigue; anxiety; anger; feelings of hopelessness, worthlessness, or guilt; and other such indicators manifest themselves, behavioral problems can develop. Recognizing the signs of stress is important for all AEMTs.
- Peer support provides a safe and nurturing environment for providers experiencing personal, emotional, or work-related problems and acts as a bridge to outside professional services. Trained peer counselors understand the unique needs of public safety providers.
- An important part of ensuring your own optimal functioning is to nurture your own wellness through proper nutrition, exercise and relaxation, smoking cessation, sleep, and disease prevention.
- AEMTs will encounter death, dying patients, and the families and friends of those who have died. Understanding the concerns of the dying patient, assisting a family following the death of a loved one, and dealing with your own feelings about death are personally and professionally important. Make appropriate statements such as “I am sorry for your loss.”
- Patients who are critically ill or injured may be anxious, afraid, angry, hostile, or depressed. They may be concerned about becoming dependent, may feel guilty, or may experience a behavioral emergency. Behave professionally, have compassion, and remain nonjudgmental.
- Critically ill or injured patients need to know who you are and what you are doing. Be sure to communicate with them, avoiding sad and grim comments and allowing for hope. Always be honest. You can often help calm a patient by locating and notifying family members.

Vital Vocabulary

acute stress reactions Reactions to stress that occur during a stressful situation.

aerosol-generating procedures (AGPs) Treatments that increase the risk for transmission of

infections that are spread through the air or by droplets.

airborne transmission The spread of an infectious agent via droplets or dust.

bloodborne pathogens Pathogenic microorganisms that are present in human blood and can cause disease in humans. These pathogens include, but are not limited to, hepatitis B virus and human immunodeficiency virus (HIV).

burnout A state of exhaustion of physical or emotional strength, which may be a consequence of chronic, unrelieved stress.

Centers for Disease Control and Prevention (CDC) The primary federal agency that conducts and supports public health activities in the United States. The CDC is part of the US Department of Health and Human Services.

communicable disease A disease that can be spread from one person or species to another.

compassion fatigue A stress disorder characterized by gradual lessening of compassion over time.

contamination The presence of infectious organisms (pathogens) or foreign bodies such as dirt, gravel, or metal in a wound.

critical incident stress management (CISM) A process that confronts the responses to critical incidents and defuses them, directing the emergency services personnel toward physical and emotional equilibrium.

cumulative stress reactions Exposure to prolonged or excessive stress.

delayed stress reactions Reactions to stress that occur after a stressful situation.

designated officer The person in the department who is charged with the responsibility of managing exposures and infection control issues.

direct contact Exposure to or transmission of a communicable disease from one person to another by physical contact.

exposure A situation in which a person has had contact with blood, body fluids, tissues, or airborne particles in a manner that suggests disease transmission may occur.

foodborne transmission The contamination of food or water with an organism that can cause disease.

general adaptation syndrome The body's response to stress that begins with an alarm

response, followed by a stage of reaction and resistance, and then recovery or, if the stress is prolonged, exhaustion.

hepatitis Inflammation of the liver, usually caused by a viral infection, that causes fever, loss of appetite, jaundice, fatigue, and altered liver function.

host The organism or person that is attacked by the infecting agent.

human immunodeficiency virus (HIV) Acquired immunodeficiency syndrome (AIDS) is caused by HIV, which damages the cells in the body's immune system so that the body is unable to fight infection or certain cancers.

immune Resistant to disease.

indirect contact Exposure to or transmission of infection from one person to another by contact with a contaminated object.

infection The abnormal invasion of a host or host tissues by organisms such as bacteria, viruses, or parasites, with or without signs or symptoms of disease.

infection control Procedures to reduce transmission of infection among patients and health care personnel.

infectious disease A medical condition that is caused by the growth and spread of small, harmful organisms within the body.

Occupational Safety and Health Administration (OSHA) The federal regulatory compliance agency that develops, publishes, and enforces guidelines concerning safety in the workplace.

pathogen A microorganism that is capable of causing disease in a susceptible host.

personal protective equipment (PPE) Equipment that blocks exposure to a pathogen or a hazardous material.

posttraumatic stress disorder (PTSD) A delayed stress reaction to a prior incident, characterized by the reliving of the stress and nightmares of the original situation. Often the result of one or more unresolved issues concerning the incident, and may relate to an incident that involved physical harm or the threat of physical harm.

standard precautions Protective measures that have traditionally been developed and recommended by the Centers for Disease Control and Prevention for use in dealing with objects, blood, body fluids, and other potential exposure risks of communicable disease.

transmission The way in which an infectious disease is spread: contact, airborne, by vehicles, or by vectors.

tuberculosis A chronic bacterial disease, caused by *Mycobacterium tuberculosis*, that usually affects the lungs but also can affect other organs such as the brain and kidneys; it is spread by cough and can lie dormant in a person's lungs for decades and then reactivate.

vector-borne transmission The use of an animal or insects to spread an organism from one person or place to another.

Chapter 3

Medical, Legal, and Ethical Issues

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Preparatory

Applies fundamental knowledge of the EMS system, safety/well-being of the AEMT, medical/legal and ethical issues to the provision of emergency care.

Medical/Legal and Ethics

- Consent/refusal of care (pp 100–106)
- Confidentiality (pp 109–110)
- Advance directives (pp 106–108)
- Tort and criminal actions (p 96)
- Evidence preservation (p 112)
- Statutory responsibilities (p 94)
- Mandatory reporting (pp 112–113)
- Ethical principles/moral obligations (pp 108–109)
- End-of-life issues (pp 100, 108)

KNOWLEDGE OBJECTIVES

1. Discuss the scope of practice and standards of care that are imposed on you as an advanced emergency medical technician (AEMT). (pp 90–92)
2. Differentiate between licensure and certification as they apply to your practice as an AEMT. (p 95)
3. Discuss the four factors that determine negligence. (pp 96–97)
4. Describe your legal duty to act. (p 96)
5. Discuss the issues of abandonment, assault, battery, kidnapping, and false imprisonment, including the implications for you as an AEMT. (pp 97–98)
6. Compare defamation, slander, and libel. (p 99)
7. Describe situations in which Good Samaritan laws or immunity would apply. (pp 99–100)
8. Define consent, including how it relates to decision-making capacity. (p 100)
9. Compare expressed consent, informed consent, implied consent, and involuntary consent. (pp 101–104)
10. Discuss consent by minors for treatment or transport. (pp 103–104)
11. Describe local emergency medical services (EMS) system protocols for using forcible restraint. (pp 104–105)
12. Explain your role and obligations if a patient refuses treatment or transport. (pp 105–106)
13. Discuss the importance of do not resuscitate orders and local protocols as they relate to the EMS environment. (pp 106–108)
14. Describe ethics and morality, including the implications for you as an AEMT. (pp 108–109)
15. Describe the relationship between patient communications, confidentiality, and the Health Insurance Portability and Accountability Act (HIPAA). (pp 109–111)

16. Explain the mandatory reporting requirements for special situations, including abuse or neglect, drug- or felony-related injuries, childbirth, and crime scenes. (pp 112–113)
17. Describe the presumptive and definitive signs of death. (pp 113–114)

18. Explain how to manage patients who are identified as organ donors. (p 115)
19. Explain the importance of medical identification devices in treating the patient. (pp 115–116)

SKILLS OBJECTIVES

There are no skills objectives for this chapter.

Introduction

A basic principle of emergency care is to do no harm. **Emergency medical care**, or immediate care or treatment, is often provided by emergency medical services (EMS) personnel, who may be the first link in the chain of prehospital care. As the scope and nature of emergency medical care becomes more complex and EMS becomes more widely available, litigation involving EMS systems will no doubt increase. All medical professionals provide care under laws. As an advanced emergency medical technician (AEMT), you also will be governed by a set of laws affecting how you treat patients. Providing competent emergency medical care that conforms with the standards of care taught to you will help you to avoid civil and criminal actions.

You must also consider ethical issues. Ethics are principles, either personal or societal, that determine what is right and wrong (discussed in more detail later in this chapter). For example, as an AEMT, should you stop and treat patients who were involved in a motor vehicle crash while you are en route to another emergency call? Should you begin cardiopulmonary resuscitation (CPR) on a patient who, according to the family, has terminal cancer? Should you release patient information to a patient's attorney over the telephone?

One of the major differences between laws and ethics is that laws have sanctions for violations that are enforceable. Laws define your obligations and protect your rights and the rights of others. It is essential, therefore, that you have a basic understanding of laws and ethics applicable to prehospital emergency care. Failure to perform your job within the law can result in civil or even criminal liability (responsibility). Practicing outside the law may also result in regulatory action within your state—for example, a disciplinary

hearing or action by your EMS agency and medical director.

Consider the following situations:

- You are transporting a patient, and while the stretcher is being loaded into the ambulance, your partner slips, the stretcher crashes to the ground, and the patient is injured.
- You are about to begin treating a child, and the father commands you to stop.

What should you do? Even when you properly render emergency medical care, at times you may be sued by a patient who seeks to obtain relief, often in the form of a monetary award, for loss of income or pain and suffering. Or, administrative action, such as suspension of your state license or AEMT certificate, may be brought against you for failure to abide by the regulations of your state EMS agency. For these reasons, you must understand the various legal aspects of emergency medical care.

This chapter reviews important legal and ethical concepts affecting your practice as an AEMT and provides the framework to help you understand these issues. However, this text cannot substitute for competent legal advice because many laws and legal obligations differ from state to state. Contact an attorney who specializes in the representation of medical professionals if you need legal advice related to your practice.

Scope of Practice

The **scope of practice** for AEMTs, which is most commonly defined by state law, outlines the boundaries for the emergency medical care you are permitted to provide for the patient. This care is based on generally accepted standards. Your medical director further defines the scope of practice by developing **protocols** (precise and detailed

plans for a regimen of therapy) and **standing orders** (local protocols, usually pertaining to a particular service or area). The medical director gives you the legal authorization to provide patient care through telephone or radio communication (online medical control) or standing orders and protocols (offline medical control). It is your responsibility as an AEMT to know your scope of practice and follow it.

Street Smarts

Treat all your patients in a kind and professional manner—the way you would like members of your own family to be treated. This courtesy is important to the patient, and it can also decrease the chance of a lawsuit being brought against you.

If you perform a procedure for which you are not authorized, then you are practicing outside your scope of practice. This action may be considered negligence (discussed later in this chapter) or, in some states, even a criminal offense (considered practicing medicine without a license). Do not confuse the scope of practice with the standard of care (discussed next).

You and other EMS providers have a legal responsibility to provide proper, consistent patient care and to report problems—such as possible liability or exposure to airborne or bloodborne pathogens or infectious disease—to your medical director immediately.

Standards of Care

The law requires you to act or behave toward other people in a certain, definable way, regardless of the activity involved. Under given circumstances,

FIGURE 3-1 Act or behave toward others in a way that shows your concern for their safety and welfare.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

you have a legal duty to act or not (discussed later in this chapter). Generally, you must be concerned about the safety and welfare of others when your behavior or activities have the potential for causing others injury or harm (**FIGURE 3-1**). The manner in which you are required to act or behave as an AEMT is called the **standard of care**.

Words of Wisdom

If you must deviate from the standard of care due to extenuating circumstances, then your best protection against legal action is good documentation. For example, if you place a patient in severe respiratory distress on a nasal cannula because he will not tolerate a nonrebreathing mask or bag-mask device, then provide a detailed explanation in the narrative portion of your patient care report (PCR).

YOU are the Provider

Part 1

You respond to a patient who has fallen. On arrival, you find an older man who states that he tripped over a lamp cord, striking his head on the corner of a table. The patient denies any pain or loss of consciousness. You note a laceration to his forehead, which you believe will require stitches. When you inform the patient of the need for medical treatment and transport, he advises you that he does not want to go to the hospital because he cannot afford the ambulance ride.

1. Can this patient refuse treatment when it is obvious that he needs stitches?
2. What can you and your partner do to attempt to persuade this patient to consent to treatment and transport?

The standard of care is established in many ways, among them published medical literature, local customs, statutes, ordinances, administrative regulations, protocols, and case law. In addition, professional and institutional standards have a bearing on determining the adequacy of your conduct.

Standards Imposed by Local Custom

The standard of care is how a reasonably prudent person with similar training and experience would act under similar circumstances (that is, with similar equipment and in the same or a similar place). For example, the conduct of an AEMT who is employed by an ambulance service would be judged in comparison with the expected conduct of other AEMTs from comparable ambulance services in the same geographic area. These standards are often based on locally accepted protocols. The prevailing custom of the community is an important element in determining the standard of emergency medical care required. Examples of prevailing customs include determining when EMS helicopters are used, how hospital destinations are selected, and protocols for spinal immobilization.

As an AEMT, you will not be held to the same standard of care as physicians or other more highly trained professionals. In addition, your conduct must be judged in the context of the given emergency situation, taking into consideration the following factors:

- Any issues concerning the safety of the patient or rescuer
- General confusion at the scene of the emergency
- The needs of other patients
- The type of equipment available

In this context, an **emergency** is a serious situation, such as injury or illness that arises suddenly, threatens the life or welfare of a person or group of people, and requires immediate intervention (**FIGURE 3-2**).

Standards Imposed by Law

In addition to local customs, standards of emergency medical care may be imposed by statutes, ordinances, administrative regulation, or case law. In many jurisdictions, violating one of these standards

FIGURE 3-2 An emergency is a serious situation that arises suddenly, threatens the life or welfare of one or more people, and requires immediate intervention.

© Rob Kim/Contributor/Getty Images Entertainment/Getty Image.

is said to create *presumptive negligence*. Therefore, become familiar with the particular legal standards that may exist in your state. In many states, the standards may take the form of treatment protocols published by a state agency.

Emergency Medical Treatment and Active Labor Act (EMTALA)

The **Emergency Medical Treatment and Active Labor Act (EMTALA)** was enacted in 1986 to combat the practice of so-called patient dumping and focuses particularly on the practice of sending women in labor to distant hospitals. Patient dumping occurs when hospital emergency department (ED) staff deny medical screening or stabilizing treatment, or when staff inappropriately transfer a person whose condition is unstable. Historically, most patient dumping occurred when hospital staff discovered that the patient did not have health insurance or was otherwise unable to pay. In recent years, *economic triage* has been introduced. This term refers to the practice of making health care decisions based on the ability of the patient or the insurance carrier to provide payment for services. Although such considerations may have a place in certain aspects of the health care field, an EMS provider should never make a decision to treat or transport based on financial considerations, regardless of the current financial state of the EMS employer. As an AEMT, your only consideration should be the needs of the patient; reimbursement issues should be addressed by billing personnel. EMS providers have

occasionally been accused of providing a lower standard of care for indigent people or those on public assistance; therefore, make sure that financial status never becomes a deciding factor in your practice. Always provide the highest possible quality of emergency medical care to all patients regardless of their financial situation.

As an AEMT, it is also important that you have a clear understanding of local protocols regarding the choice of hospitals to which you may transfer your patient. In some rural areas, only one hospital may be available, but in other places several options may be available. Some EMS systems simply require you to transfer the patient to the nearest hospital. In other systems, however, protocols dictate that hospital selection must be based on the specific needs of the patient. For example, some patients may require the services of a trauma center, a children's hospital, or a hospital with cardiac catheterization capabilities. Depending on local protocols, you may be able to make the choice of destination alone, whereas in others you may be required to consult with medical control in making such decisions. It is important to become familiar with the protocols in your area of practice.

EMTALA issues are regulated by the Centers for Medicare and Medicaid Services (CMS) and carry severe monetary penalties—up to and including loss of Medicare funding—for hospitals that fail to comply.¹ The CMS also issues severe fines for hospitals and physicians who violate EMTALA provisions. In addition, EMTALA allows private citizens to sue for violations of the act. Under most circumstances, neither an ambulance service nor an AEMT can be sued or charged with a violation under EMTALA. An ambulance service that is owned by a hospital, however, may be subject to a claim under EMTALA in certain cases.

EMTALA guarantees a medical screening exam, and treatment to stabilize any emergency medical conditions found, to any patient presenting to a hospital that has an ED. It prohibits discrimination for any reason, including the ability to pay. Some urgent care centers may also be covered by EMTALA. Although EMTALA does not directly regulate EMS providers, EMS is often the vehicle—both figuratively and literally—by which patient dumping takes place.

EMTALA also regulates patient transfers and applies to both the sending and receiving facilities.

Words of Wisdom

EMTALA legislation requires that every patient must receive emergency medical treatment—regardless of the person's ability to pay for medical treatment when it is received.

Never transfer a patient who needs emergency medical care that falls outside your scope of practice. You must feel comfortable that the patient is stable enough to transfer. A transferring hospital staff has an obligation to ensure the transferring ambulance and crew are capable of meeting the needs of the patient during transfer, and should request an ambulance that is appropriately staffed and equipped. It would be a potential EMTALA violation if hospital staff requested a basic life support (BLS) ambulance and crew to transport a patient with a serious cardiac condition who required cardiac monitoring and the administration of medication during the transport. Should a patient need a higher level of care, it is the responsibility of the transferring hospital to provide someone to ride along (a nurse, respiratory therapist, or even a physician). Make sure you have received all appropriate paperwork before leaving on a patient transfer, including all pertinent medical records, laboratory results, radiographs, and other documents. When you arrive at the receiving hospital, that hospital staff should have a bed ready for the patient, after agreeing to accept the patient.

Professional or Institutional Standards

In addition to standards imposed by law, professional or institutional standards may be used as evidence in determining the adequacy of your conduct as an AEMT. Professional standards include recommendations published by organizations and societies that are involved in emergency medical care. For example, consider the standard of care for BLS and CPR (**FIGURE 3-3**). In the past, the American Heart Association (AHA), in concert with the International Liaison Committee on Resuscitation, came together to revise the *Guidelines for Cardio-pulmonary Resuscitation and Emergency Cardiac Care* every 5 years. However, it was recognized in the 2015 guidelines that a 5-year cycle is insufficient

FIGURE 3-3 Many standards of care are imposed on you as an AEMT, such as those for performing cardiopulmonary resuscitation. Learn the standards of care for your level of training and organization.

© Jones & Bartlett Learning, Courtesy of MIEMSS.

to keep pace with the rapidly evolving research in resuscitation science, and you should expect to see updates released more frequently in the future.

Institutional standards include specific rules and procedures of the EMS system, ambulance service, or organization with which you are affiliated. Be familiar with the standards of your organization. The standards formulated for a specific agency should be reasonable and realistic so that they do not impose an unreasonable burden on EMS providers. Providing the best emergency medical care should be your goal as an AEMT, but it is unrealistic to have institutional standards that demand the best care.

Ordinary care is a minimum standard of care. In general, it is expected that anyone who offers assistance during an emergency will exercise reasonable care and act prudently. If you act reasonably, according to the standard practices you have been trained to use, then you can likely avoid liability. If you deviate from these standards, then you may be liable for civil action and possibly criminal prosecution (discussed later in this chapter). In addition, state regulatory agencies that oversee EMS operations can sanction you for deviating from the standard of care.

Standards Imposed by Textbooks

In the course of a lawsuit, an attorney will often ask an AEMT if they recognize various textbooks as being authoritative works in the field of EMS. Because virtually all EMS textbooks follow standards established by the National Highway Transportation

Safety Administration, these textbooks are often recognized as contributing to the standard of care that is followed by AEMTs. Local protocols or state standards may differ from material presented in textbooks. When such differences occur, you are bound to follow local protocols.

EMS-Enabling Legislation

Most states now have what is called EMS-enabling legislation, which defines how EMS is structured and designates responsibilities to government agencies. These laws also provide the state-based framework for the AEMT's actual practice—what you are permitted to do in the field. For example, EMS legislation may define the need for a medical director and may also define the scope of practice for the different levels of EMS personnel. Familiarize yourself with the EMS legislation in your state and any regulations that flow from those statutes.

Standards Imposed by States

Individual states have their own requirements for licensure or certification (discussed next). Most states now recognize the National Registry of Emergency Medical Technicians as their certifying agency; however, check with the state in which you work to learn its specifications. An overview of this process follows.

Medical Practice Act

The practice of medicine is defined as the diagnosis and treatment of disease or illness. In some states, EMS personnel are exempt from the licensure requirements of the Medical Practice Act because an AEMT is regarded as a nonmedical professional. This act usually defines the minimum qualifications of those who may perform various health services, defines the skills that each type of practitioner is legally permitted to use, and establishes a means of licensure or certification for different categories of health care professionals. Requirements for relicensure or recertification based on continuing education and other factors may also be included in the Medical Practice Act.² As an AEMT, you must be aware of the standards established by legislation in your state so that you can provide emergency medical care that is consistent with those standards.

When you are unsure of the proper care, always contact medical control for orders. Question any order that is unclear or seems inappropriate. Do not blindly follow an order that is incorrect or does not make sense to you. The physician may have misunderstood or may have missed part of the report. In that case, the physician may not be able to respond appropriately to the patient's needs.

Street Smarts

Medical control consists of the physician at the receiving facility who answers your call and provides guidance for patient care or allows you to administer certain medications that are within your scope of practice. Always echo (repeat) orders back to ensure complete understanding on both parts and do not blindly follow orders that seem inappropriate for your patient.

Certification and Licensure

Some states provide certification or licensure of people who perform emergency medical care. These terms are often confused. **Certification** is the process by which an individual, institution, or program is evaluated and recognized as meeting certain predetermined standards to ensure safe and ethical patient care. It generally refers to a certain level of credentials based on hours of training and assessment exams and addresses criteria met for a minimum competency. Certification may be granted by a government agency or by a private organization such as the AHA or the American Red Cross. The fact that you have received a certification from a private organization does not necessarily mean that you have authority to practice the skills included in that certification. **Licensure** is the process by which a competent authority, usually the state, grants permission to practice a job, trade, or profession. A license itself is a privilege granted by a government authority on certain conditions. You must comply with the government's requirements for professional behavior, continuing education, and licensure renewal, or risk losing that privilege. The rights and privileges conferred by licensing in one state may not be conferred in other states.

Another concept that you may encounter is that of **credentialing**. Credentialing is an established

process to determine the qualifications necessary to be allowed to practice a particular profession or to function as an organization. Credentialing may be adopted by a specific EMS agency as part of its employment requirements. For example, although you may be licensed as an AEMT by your state, the agency from which you are seeking work may impose additional requirements as part of its eligibility standards. Common examples include certification in CPR or trauma.

Negligence

Negligence is the failure to provide the same care that a person with similar training would provide in the same or similar situation. It is a deviation from the accepted standard of care that may result in further injury to the patient. Some states differentiate between ordinary negligence and gross negligence. **Gross negligence** is defined as conduct that constitutes a willful or reckless disregard for a duty or standard of care.

Negligence is commonly divided into three categories: (1) malfeasance, (2) misfeasance, and (3) nonfeasance. **Malfeasance** occurs if you perform an act that you are not authorized to do, such as a medical intervention that is outside of the scope of practice. **Misfeasance** occurs if you perform an act that you are legally permitted to do, but you do so in an improper manner. For example, you administer a medication that is clearly within the scope of practice, but you accidentally calculate an incorrect dose. **Nonfeasance** occurs if you fail to perform an act that you are required or expected to perform. Failure to perform CPR when a patient goes into cardiac arrest would be an example of nonfeasance.

In some cases, negligence may be so obvious that it does not require extensive proof. **Res ipsa loquitur** is Latin for "the thing speaks for itself." Under this theory, the injury could only have been caused by negligence. For example, if you drop the stretcher while the patient is unresponsive and the patient sustains an injury, then the patient may prevail in a lawsuit against you by showing that he was under your care, that he sustained an injury, and that his injury would not have occurred unless negligence was present.

In rare cases, the theory of **negligence per se** may be used if the conduct of the person being sued is alleged to have occurred in clear violation of a

statute. For example, if you were to perform a paramedic skill, such as endotracheal intubation, the plaintiff might allege that this act was negligence per se. In that case, the plaintiff would not have to establish the circumstances surrounding your conduct. The plaintiff would not need to show that the procedure was inappropriate because you clearly exceeded your scope of practice as an AEMT.

A legal action of that sort is called a **civil lawsuit**—that is, an action instituted by a private person or entity (the **plaintiff**) against another private person or entity (the **defendant**)—and the wrongful act that gives rise to a civil lawsuit is called a **tort**. All forms of negligence come under this general category of law. The law recognizes two classifications of torts: unintentional torts (commonly referred to as negligence) and intentional torts (those that describe an intent to cause harm). Torts are simply defined as civil wrongs and are not within the jurisdiction of the criminal courts. Examples of tort actions other than negligence are lawsuits for defamation of character and invasion of privacy (discussed later in this chapter).

Words of Wisdom

Contributory negligence is a legal defense that may be raised when the defendant feels that the plaintiff has done something that contributed to their own injuries. For example, you are treating a patient with chest pain and you feel that the administration of aspirin is indicated. You ask the patient if he is allergic to aspirin and he says no. Shortly after you administer the aspirin, the patient develops the signs and symptoms of a severe allergic reaction. Later in the hospital, the physician advises you that the patient's medical history indicates that the patient has an allergy to aspirin. The patient states that he forgot he was allergic to aspirin. In this case, the defense of contributory negligence might be raised because it was the patient's forgetfulness and his denial of an aspirin allergy that contributed to his allergic reaction.

Determination of negligence is based on the following four factors:

1. Duty
2. Breach of duty
3. Damages
4. Proximate cause

All four elements must be present for the legal doctrine of negligence to apply and for the plaintiff to prevail in a lawsuit against an EMS system or provider. These elements are discussed in more detail in the following sections.

Duty

Duty is prescribed by law. It is an obligation to provide patient care in a manner that is consistent with the standard of care established by training and local protocols. Responsibility comes from either statute or function. A bystander is under no obligation to assist a stranger in distress and therefore has no legal duty to act. Instances in which you have a legal duty to act may include the following:

- You are dispatched to or witness an emergency situation while on duty.
- The policy of your service or department states that you must assist in any emergency.

After your ambulance responds to a call or treatment is initiated, you have a legal duty to act. In most cases, if you are off duty and come upon a crash, then you are not legally obligated to stop and assist patients. However, laws vary from state to state. Be familiar with the laws and policies that apply in your service area. If you choose to intervene while off duty, then continue to provide competent care until a medical professional with an equal or higher level of training assumes care of the patient.

Most services have a policy addressing the discovery of another incident while en route to a call or en route to the hospital with a patient. The key to legal duty is to make sure the appropriate personnel are dispatched if you cannot stop to render assistance due to the severity of the patient you are currently treating.

Breach of Duty

The second element a patient must prove for a lawsuit to be successful is that the AEMT failed to perform within the standard of care. A **breach of duty** occurs when the person accused of negligence failed to act as another person with similar training would have acted under the same or similar circumstances. Breach of duty may involve doing less than the person was trained to do (an error of omission; ie, an AEMT who fails to splint an injured extremity) or doing more than the person was trained to do

(an error of commission; ie, an AEMT who sutures a laceration when doing so is not within the scope of practice).

In a lawsuit, a jury will listen to the testimony of expert witnesses on both sides and ultimately decide whether your care was reasonable or not. These expert witnesses will provide multiple sources on which to base their testimony about whether your care was reasonable. Those sources will include their own training and experience; your training, experience, and continuing education; textbooks; protocols; national standards; standard operating procedures; and the PCR. Good documentation will go a long way to prove your high standards of care.

Damages

The objective of a civil lawsuit is usually some sort of compensation (**damages**) when a patient is physically or psychologically harmed in some noticeable way. Although physical injury is usually part of any lawsuit for medical negligence, patients may also claim damages for emotional distress, loss of income, loss of enjoyment of life, loss of spousal consortium, loss of household services, and loss of future earning capacity. Patients will have to show that your actions were proximate causes of each of these losses.

Proximate Cause

A reasonable cause-and-effect relationship must exist between the breach of duty and the injury sustained by the patient. **Proximate cause** is a legal term that, in the sense of medical malpractice, essentially considers whether the alleged harm to the patient would have occurred “but for” the negligent act. If the injury would have still occurred regardless of the alleged act of malpractice, then no valid claim exists.³

If you have a legal duty to act and abuse it, causing harm to another individual, then you, your EMS agency, and/or medical director may be sued for negligence. Even in cases in which the AEMT had a legal duty to the patient, and the AEMT breached the standard of care, a plaintiff must still link the act that fell below the standard of care directly to the injury by showing that the act (or failure to act) proximately caused the harm. Proving that an act or a failure to act caused an injury is the most difficult part of a lawsuit. For example, imagine that

you are treating a patient from a motor vehicle crash who has a spinal cord injury and you drop the stretcher during patient care. The patient may try to show that their spinal cord injury resulted from the dropped stretcher and not from the crash itself. In such a case, careful documentation of the patient’s neurologic status at the time you first encountered the patient would be essential to your defense.

Abandonment

Abandonment is a form of negligence that involves the termination of emergency medical care without the patient’s consent. (Consent is discussed later in this chapter.) The term also implies that the patient had a continuing need for medical treatment and that the abrupt termination of treatment was the cause of subsequent injury or death. Therefore, after you have initiated patient care, you have assumed a duty that must not cease until an equally competent person with an equal or higher level of training assumes responsibility (that is, another AEMT, a paramedic, a nurse, or a physician). Abandonment is a legally and ethically serious matter that exposes the patient to harm and can result in civil action against you.

For example, suppose you arrive at the scene of a single-car crash and begin emergency medical care of two injured patients. A passerby tells you of a two-car collision farther down the road in which five people are injured. You turn over care of the two injured patients from the first crash to the passerby and leave to go to the other collision site. Abandonment has occurred because you did not turn over the care of the patients to a person with a level of training equal to or higher than yours. Consider the following general questions when you are faced with making a decision such as this one:

- What consequences may develop from your actions?
- How might the patient’s condition worsen if you leave?
- Does the patient need emergency medical care?
- Are you neglecting your duty to your patient?
- Is the person assuming care capable of providing the level of care needed by the patient?
- Are you abandoning the patient if you leave the scene?
- Are you violating a standard of care?
- Are you acting prudently?

Surprisingly, abandonment may also take place in the ED where you drop off your patient. A part of your obligation as an AEMT is to provide hospital personnel with a report of your assessment findings, the emergency medical care you provided, and any changes in patient status that occurred during transport to the hospital. The failure to file a PCR could result in a delay in treatment or a misdiagnosis. In such a case, a claim for abandonment could be filed against you. It is always a good idea to obtain a signature on your PCR from the person accepting transfer of care at the hospital. This step will help protect you from allegations of abandonment.

Words of Wisdom

A mass-casualty incident during which you perform triage does not constitute abandonment. The nature of triage is to do the most good for the greatest number of people, accomplished by a simple, rapid evaluation and categorization. Triage is discussed further in Chapter 41, *Incident Management*.

Assault, Battery, Kidnapping, and False Imprisonment

Sometimes the same allegedly wrongful or harmful act that gave rise to a lawsuit may also result in criminal prosecution. A **criminal prosecution** is an action taken by the government against a person the prosecutors feel has violated criminal laws. In a criminal case, the government must prove guilt beyond all reasonable doubt to a jury. If the government succeeds, then the defendant can be fined, imprisoned, or both.

The criminal laws most likely to apply to pre-hospital care include assault, battery, kidnapping, and false imprisonment. Examples of these actions include using improper restraining methods, making physical contact with a patient before asking for permission from the patient, or transporting a patient without the person's consent.

- **Assault** is defined as threatening a person or causing a person fear of immediate bodily harm without the person's consent—regardless of whether the threat of harm is actually carried out. Threatening to start an intravenous

(IV) line on a patient using a large needle, or threatening to restrain a patient who does not want to be transported, may be considered assault.

- **Battery** is unlawfully touching another person. Making physical contact with a patient before asking if you may touch the person may be considered battery. Just about any act of medical treatment performed without consent may be considered assault or battery or both, because such acts constitute a threat to the patient's bodily security ("Now I'm going to stick you with this needle . . .") and an unsanctioned contact with the patient's body. Assault and battery can be either civil or criminal in nature. To prosecute a criminal charge of assault or battery, the prosecution generally needs to prove the intent to cause harm. In a civil case, plaintiffs need only establish that the conduct took place without their consent.
- **Kidnapping** is the seizing, confining, abducting, or carrying away of a person by force. In theory, this might include a situation where a patient is transported against their will. Criminal charges of false imprisonment or kidnapping are rarely filed against EMS providers. Civil lawsuits alleging false imprisonment or kidnapping are more common and usually arise out of circumstances in which the patient claims to have been transported or restrained against their will. In reality, criminal charges of kidnapping are almost unheard of in EMS because the EMS provider is almost always acting in a good faith effort to provide care to the patient. It is far more likely that an EMS provider could be the target of a civil lawsuit for false imprisonment.
- **False imprisonment** is defined as the unauthorized confinement of a person that lasts for an appreciable period. Consider a patient who withdraws consent during transport and demands to be let out of the ambulance. If you refuse, then you may be accused of false imprisonment. Your best protection against these charges is to obtain informed consent for almost everything you do (discussed later in this chapter). Consult your medical director if you have questions or doubts about a specific situation.

Defamation, Libel, and Slander

As an AEMT, you may also be sued for **defamation**, which is intentionally making a false statement through written or verbal communication that injures a person's good name or reputation. **Libel** is making a false statement in the written form that injures a person's good name (reputation or standing in the community). When you write your PCR, avoid using terms that may be considered judgmental or offensive, such as "The patient appears to be drunk." Instead, use descriptions such as "The patient walks with an unsteady gait," or "The patient's words were slurred." Whatever your personal views, think about the way in which your PCR would read in court. Do not let thoughtless comments become evidence against you.

Slander is making a false verbal statement that injures a person's good name. Once again, avoid using terms that could be considered judgmental or offensive to the patient when you are passing along prehospital care information to ED personnel. Always keep in mind that your patient is someone's son or daughter, husband or wife, brother or sister, or father or mother. Consider how you would like information about members of your own family to be presented to the hospital staff.

Good Samaritan Laws and Immunity

All states have **Good Samaritan laws**, which are based on the common law principle that when you reasonably help another person, you should not be liable for errors and omissions that are made while giving good faith emergency medical care. However, Good Samaritan laws do not necessarily protect you from a lawsuit. Good Samaritan provisions vary significantly from state to state. For example, some laws provide Good Samaritan protection for anyone who stops to render aid during an emergency, whereas other laws only provide protection for those with no medical training. Good Samaritan statutes in some jurisdictions provide **immunity** from a lawsuit, whereas others provide an affirmative defense if you are sued for rendering care. In most cases, Good Samaritan laws do not prohibit the filing of a lawsuit, nor do they pertain to acts that could be considered

Words of Wisdom

To be protected by the provisions of a Good Samaritan law, you must meet several conditions:

1. You acted in good faith in rendering care.
2. You rendered care without expectation of compensation.
3. You acted within your scope of practice.
4. You did not act in a grossly negligent manner.

wanton, gross, or willful negligence, or if care is provided for remuneration (any sort of payment, monetary or otherwise).

Another group of laws grants immunity from liability to official EMS providers in specific circumstances. These laws, which vary from state to state, do not provide immunity when injury or damage is caused by gross negligence or willful misconduct. In most cases, immunity statutes apply to EMS systems that are considered government agencies.

An abiding principle of English law is that you cannot sue the queen (or king) because "the queen can do no wrong." In the United States, this concept, called sovereign immunity, has taken the form of legislation that identifies only limited types of lawsuits that can be filed against government agencies. EMS personnel working for government agencies, such as a fire department, also have some **governmental immunity** for their actions. Governmental immunity generally applies only to EMS systems that are operated by municipalities or other government entities. If your service is covered by governmental immunity, then it may mean that you cannot be sued at all, or it may limit the amount of the monetary judgment that the plaintiff may recover. State laws vary significantly. Understand the laws that apply in your state.

The **statute of limitations**, which limits the number of years after an incident during which a lawsuit can be filed, may also aid in protecting you from litigation. It is set by law, may differ for cases involving adults and children, and varies from state to state.

Most states have also adopted specific laws granting special privileges to EMS personnel, authorizing them to perform certain medical procedures. Many states also grant partial immunity to EMS providers, physicians, and nurses who give emergency instructions to EMS personnel via radio

Words of Wisdom

The AEMT in Court

The **discovery** phase of a legal case is an opportunity for both sides to obtain information that will enable the attorneys to have a better understanding of the case, which will assist in negotiating a possible settlement or in preparing for a trial. Discovery may include interrogatories, depositions, requests for documents, and physical exams. **Interrogatories** are written questions that each side sends to the other, and **depositions** are statements from parties and witnesses taken under oath.

At trial, each side will have an opportunity to present evidence. After both sides have concluded, a judge or jury will render a decision or verdict. If a judgment is rendered against you or your service, then the plaintiff may be awarded compensatory or punitive damages.

Compensatory damages are intended to compensate the plaintiff for the injuries sustained, such as medical bills, damages to personal property, lost earnings, and physical or emotional pain and suffering. **Punitive damages** are not commonly awarded in cases of negligence and are reserved for those cases in which the defendant acted intentionally or with a reckless disregard for the safety of the public.

Street Smarts

When you provide testimony in any phase of a lawsuit, it is best to be brief. Answer only the specific question that is asked based on your review of the patient report or your vivid memories of the incident. It is perfectly acceptable to answer "I don't know" or "I can't recall" if you are unsure. Opinions and elaborations subject you to challenges by the attorneys and can make you and your testimony seem less believable to the judge or jury.

or other forms of communication. Consult your medical director or state EMS agency for more information about the laws in your area.

Consent

Under most circumstances, consent is required from every responsive, mentally **competent** adult before emergency medical care can be started. Remember, any touching of a patient's body

without consent may give rise to charges of assault and battery. A person receiving emergency medical care must first give permission, or **consent**, for treatment. If a person is alert, rational, and capable of making informed decisions, then the person has a legal right to refuse emergency medical care, even though ill or injured. A patient may also consent to some aspects of emergency medical care and deny consent to others. If a patient refuses emergency medical care, then you may not care for the patient. In fact, doing so may be grounds for criminal and civil action. Consent can be either expressed (actual) or implied.

The foundation of consent is **decision-making capacity**, the ability of patients to understand the information you are providing, coupled with their ability to process that information and make an informed choice regarding medical care that is appropriate for them. You have a variety of tools that you can use to evaluate decision-making capacity, but the best one is your ability to talk to patients to find out whether they understand what is happening to them. In addition, if pulse oximetry and blood glucose measurements are outside normal ranges, then these readings can provide measurable information regarding your patient's ability to understand and communicate. Detailed documentation of decision-making capacity is important to include in your PCR to show that the patient was able to understand your proposed treatment plan.

Keep in mind that the law allows the patient to make choices that may seem medically unsound and that might endanger the patient's life. The right of patients to make decisions concerning their care and to decide how they want their end-of-life medical care provided to them is known as **patient autonomy**. Because the assistance of medical technology has made the distinction between life and death more imprecise, several high-profile cases have brought the issue of patient autonomy to the forefront of the medical ethics debate in the past 20 years. For example, the legal case involving Terri Schiavo from 1990 to 2005 demonstrated that the courts will ultimately support the right of the patient, or the patient's closest relative, to make end-of-life decisions (**FIGURE 3-4**). Terri Schiavo did not prepare a written advance directive about her end-of-life care, which put the case in the hands of the state and federal courts. Advance directives are discussed later in this chapter.

FIGURE 3-4 Because Terri Schiavo did not prepare an advance directive specifying the end-of-life care she wanted to receive, her case became a battleground between family members who held different viewpoints about care of the terminally ill.

Expressed Consent

Expressed consent (or actual consent) is a type of consent that occurs when patients acknowledge that they want you to provide emergency medical care or transport. Expressed consent may be either verbal or nonverbal. For example, if you ask a patient if you can check their blood pressure and the patient extends an arm to you, then the patient is expressing nonverbal consent.

From a legal and ethical standpoint, you should obtain consent that is not only *expressed* but also *informed* before caring for any adult patient who has decision-making capacity. To obtain **informed consent**, use the following steps:

1. Describe the suspected illness or injury to the patient.
2. Describe the treatment you would like to administer, and list the potential risks associated with the proposed treatment.
3. If the patient adamantly refuses to be transported, discuss any alternative types of

Words of Wisdom

The terms decision-making capacity and competence are often used interchangeably, but *competence* is generally regarded as a legal term, and determinations regarding competence are typically made by a court of law. *Decision-making capacity* is more commonly used in health care to determine whether or not a patient is capable of making health care decisions. Consider the following factors when determining a patient's decision-making capacity:

- Is the patient's intellectual capacity impaired by a mental limitation or any type of dementia?
- Is the patient of legal age (age 18 years in most states)?
- Is the patient impaired by alcohol or drug intoxication or serious injury or illness?
- Does the patient appear to be experiencing significant pain?
- Does the patient have a significant injury that could distract the person from a more serious injury? (For example, a significant non-life-threatening injury can cause extreme pain and distract the patient from neck pain, which could indicate a more serious injury.)
- Does the patient exhibit any hearing or visual problems?
- Is a language barrier present? Do you and your patient speak the same language?
- Does the patient appear to understand what you are saying? Does the patient ask rational questions that demonstrate an understanding of the information you are trying to share?

treatment available and recommend that the person be seen by a physician regardless of the mode of transportation.

4. Advise the patient regarding any potential consequences of refusing treatment.

Often, the prehospital environment requires that consent be obtained more quickly than in the hospital setting. The key is to ensure that your patient understands what you are trying to do and grants you permission to treat. Informed consent is valid if given verbally, but it may be difficult to prove at a later point in time. It is important to document how you obtained informed consent in the event that legal issues arise later. The legal basis for this doctrine rests on the assumption that the patient has a right to determine what is to be done with their body (patient autonomy). The patient must be of legal age (age 18 years in most states) and able to

make a rational decision. Paramedics will often provide additional information if advanced life support (ALS) interventions are necessary. In such cases, a greater potential exists for adverse effects and other responses associated with drug administration and other forms of advanced care.

Street Smarts

Many challenges can get in the way of giving patients the information they need to make a decision, such as a language barrier, emotional state, and mental ability.

A patient might agree to only certain types of emergency medical care. For example, a patient might agree to receive oxygen and transport but might refuse insertion of an IV line. An injured person might agree to emergency medical care at home but might refuse to be transported to a medical facility.

Implied Consent

When individuals are unresponsive or otherwise unable to make a rational, informed decision about their medical care, and are therefore unable to give consent, the law assumes that the patients would consent to care and transport to a medical facility if they were able to do so (FIGURE 3-5). This principle is called **implied consent**. Implied consent is limited

FIGURE 3-5 When a serious threat to life exists and the patient is unresponsive or otherwise unable to give consent, the law assumes that the patient would give consent to emergency medical care and transport to the hospital.

© Murray Wilson/Fotolia.com.

to true emergency situations and is appropriate when the patient is unresponsive, delusional, exhibiting an altered mental status as a result of drug or alcohol use, or is otherwise physically unable to give expressed consent. The principle of implied consent is also known as the **emergency doctrine**, which allows EMS personnel to act in critical situations without danger of recrimination. However, the exact situations or conditions that represent a “serious threat to life” may be unclear, and it may become a legal question. Use of the emergency doctrine may result in legal proceedings and a

YOU are the Provider

Part 2

Your primary survey reveals the following:

Recording Time: 1 Minute

Appearance	Calm; seated on chair with laceration noted to forehead; minimal bleeding
Level of consciousness	Alert and oriented to person, place, time, and event
Airway	Patent
Breathing	Within normal limits
Circulation	Strong radial pulses; skin warm and dry

- What concerns do you have regarding the patient’s mechanism of injury?
- What alternative options do you have regarding transport to the ED?

medicolegal judgment against you, which should be defended by your best efforts to obtain consent and a thoroughly documented PCR. Medicolegal is a term that relates to medical jurisprudence (law) or forensic medicine. In most instances, the law allows the spouse, a close relative, or next of kin to give consent for a person who is unable to do so, and you should make every effort to obtain consent from an available relative before treating based on implied consent. However, never delay treatment if the patient has imminently life-threatening injuries. A patient's refusal of your offer to provide emergency medical care may also be implied if the patient physically resists. Seek help in the form of online medical direction to help convince the patient to allow transport to the hospital. A physician online can also authorize an emergency petition to bring the patient to the ED against their will if it appears the patient is not competent to refuse care.

Finally, it is important to understand that if a patient being treated based on implied consent were to become alert and capable of making an informed decision, then the emergency doctrine of implied consent would no longer apply. This situation is commonly seen with patients with hypoglycemia who are initially unresponsive and then regain complete use of their mental faculties when their glucose levels are returned to normal.

Documentation and Communication

If a patient with a potentially life-threatening condition refuses care, the burden is on the EMS provider to clearly document that the patient understands the risks and is not mentally compromised by alcohol, drugs, or disease at the time of the refusal.

Minors and Consent

Because a minor might not have the wisdom, maturity, or judgment to give valid consent, the law requires that a parent or legal guardian give consent for treatment or transport when available (**FIGURE 3-6**). In every state, if a parent cannot be reached to provide consent, then health care providers are allowed to give emergency medical care to a child. However, in some states, a minor can give valid consent to receive emergency medical

FIGURE 3-6 The law requires that a parent or legal guardian give consent for treatment or transport of a minor. However, never withhold life-saving emergency medical care.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

care, depending on the minor's age and maturity level. An **emancipated minor** is a person who, despite being under the legal age in a given state (in most cases, age 18 years), can be legally treated as an adult based on certain circumstances. For example, many states consider minors to be emancipated if they are married, if they are members of the armed services, or if they are parents. Minors may also be considered emancipated if they are living away from and no longer relying on their parents for support. Minors who are a parent may also give consent for their own child. A court may issue an order declaring a minor to be emancipated, but such a situation is uncommon. Know the laws of your state concerning the issues surrounding emancipation.

Also be aware of the legal principle known as **in loco parentis**. This term literally means “in the place of the parent.” This principle may apply in school, day care, or summer camp if a parent is unavailable. The school administrator or day care director may make treatment and transportation decisions on behalf of the minor. Make every effort to immediately contact the parent or legal guardian, but do not withhold life-saving emergency medical care for a minor because a person authorized to give consent is unavailable.

A particularly difficult circumstance can arise if a parent or legal guardian refuses to grant consent to treat a minor who clearly requires life-saving or limb-saving treatment. Although adults clearly have the right to refuse treatment for themselves,

state laws generally do not permit a parent or guardian to deny treatment to a minor. In fact, the failure of a parent or guardian to allow such treatment may constitute neglect. If confronted with such a circumstance, then notify law enforcement and medical control. State law may permit the state to assume custody of the minor for the purposes of ensuring that necessary emergency treatment be provided.

Special Populations

In the absence of a parent or legal guardian, minors are treated under implied consent in critical situations. You must never withhold life-saving care. However, if the child does not have a life-threatening illness or injury, then proper consent for treatment must be obtained prior to providing emergency medical care.

Words of Wisdom

Every report should be as detailed and accurate as possible, especially reports of patient refusals. When a patient, parent, or legal guardian refuses treatment or transport, a thorough PCR and an official refusal form will help to protect you from legal action. Have the patient or other refusing party sign the form, and ask an impartial observer (eg, a law enforcement officer, if available) to witness the signature if possible. Document in the PCR what you have done to ensure an informed refusal, and note the involvement of medical control in the situation. Be sure to submit the refusal form with your PCR. Reporting requirements are discussed in detail later in this chapter.

Involuntary Consent

Some EMS personnel incorrectly use the term involuntary consent to refer to situations in which a law enforcement officer or a legal guardian grants permission to treat someone who is under arrest (or otherwise in custody), mentally ill, developmentally delayed, incapacitated, a minor, or for other reasons. Involuntary consent is an oxymoron because consent can never be involuntary. People under arrest or in prison do not necessarily lose their right to be involved in medical treatment decisions. It is not uncommon for a law enforcement officer to direct

EMS personnel to treat a person under arrest, but you should continue to follow informed consent guidelines. If a prisoner refuses treatment, then involve medical control. Remember that when a true emergency exists, you can assume that implied consent exists.

Forcible Restraint

Forcible restraint is the act of physically subduing a patient to prevent harm. Forcible restraint may be necessary if you are confronted with patients who are in need of medical treatment and transportation but are physically violent and present a significant risk to others. This behavior may result from an underlying psychiatric or behavioral condition, the effects of drugs or alcohol, or a medical condition such as a head injury or hypoxia. Forcible restraint of a patient may be required before you can give emergency medical care. If you believe that a patient will injure himself, herself, or others, then you can legally restrain the patient. However, you must consult medical control (either online or off-line, depending on local protocol) for authorization to restrain, or contact law enforcement personnel who have authority to restrain people. In some states, only a law enforcement officer may forcibly restrain a person (**FIGURE 3-7**). Understand the local laws. Restraint without authority exposes you to civil and criminal penalties. Restraint may be used only in circumstances of risk to the patient, yourself, or others.

FIGURE 3-7 Know the local laws about forcible restraint of a patient. In some states, only a law enforcement officer has the authority to restrain a patient.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Your service should have clearly defined protocols pertaining to situations involving restraint. After restraints are applied, they must not be removed en route—even if the patient promises to act calmly. It is also important to monitor the restrained patient closely for any signs of breathing difficulty and to never restrain a patient in a prone position. It is possible to suffocate the patient if they are face-down (creating positional asphyxia) or if a mask placed over the patient's face blocks airflow.

Remember that if the patient is responsive and the situation is not urgent, then consent is required.

Safety

If you are faced with a potentially violent patient, ensure the scene is safe and law enforcement is present before proceeding.

The Right to Refuse Treatment

As discussed previously, adults who are alert, rational, and appear to have decision-making capacity have the right to refuse treatment or withdraw from treatment at any time, even if doing so may result in death or serious injury. Such patients present you with an ethical dilemma. Should you provide emergency medical care against their will? Should you leave them alone? Calls involving refusal of treatment are commonly litigated in EMS and require you to proceed cautiously. If you leave a patient alone, then you risk being accused of negligence or abandonment if the person's condition becomes worse. You may also face charges of false imprisonment if you transport a patient against their wishes.

If a patient refuses treatment or transport, then you must ensure that the person understands, or is informed about, the potential risks, benefits, treatments, and alternative treatments (due diligence). To refuse, the patient must be alert and oriented to person, place, time, and event. Ensure the patient does not have an altered mental status, and extensively document your assessment findings. If you have any doubts, then consult medical control for direction. The most prudent approach is to inform the patient in a calm and sympathetic manner of the possible consequences of refusing treatment.

Keep in mind that many people who refuse medical treatment do so out of fear and emotional distress, and you need to recognize and manage the patient's stress in an understanding way. It is not uncommon for patients to refuse treatment and transport to the hospital because of concern for the costs associated with the ambulance and hospital treatment. Patients may also refuse treatment and transport because of denial that something is wrong. Addressing these concerns can be challenging for you and may require all of your "people skills." Remember the phrase: "It never hurts to have these things checked out."

Let patients know that your chief concern is their well-being, and tell them that it is all right to change their mind. Urge patients to seek

Words of Wisdom

In general, any patient with an altered mental status or unstable vital signs probably cannot be considered able to refuse transport to the hospital. Become proficient in quickly establishing whether a patient has decision-making capacity. The criteria for determining mental competence should be clearly spelled out in the protocols of every ambulance service. As a rule, such criteria will include the following:

- The patient is oriented to person, place, time, and event.
- The patient responds to questions appropriately.
- The patient does not exhibit significant mental impairment from alcohol or drug intoxication, head injury, or organic illness. (Ask the family or bystanders, if present, if this behavior is considered normal for the patient.) What constitutes significant mental impairment is a subjective judgment call.
- The patient demonstrates to you that they understand the nature of their condition and the risks of refusing treatment and transport. This demonstration can take place only after the patient has been thoroughly informed of your assessment findings and the risks associated with refusal.
- The patient can describe a reasonable plan for follow-up care.
- The patient's oxygen saturation levels are within normal limits.
- The patient's blood glucose levels are within normal limits.
- The patient does not appear to have serious, distracting injuries that might impair their decision-making capacity.

further medical evaluation from the physician of their choice. Help them make concrete plans for follow-up. As discussed previously, some patients will consent to treatment but refuse transport. If you have exhausted all efforts to convince a patient to accept treatment and transport and the patient still refuses, try to make sure someone will be with the person after you leave.

As discussed, although adults have the right to refuse treatment for themselves, state laws generally do not permit a parent or legal guardian to deny treatment to a minor. In this situation, consider the emotional impact of the emergency on the parent or guardian's judgment. You can usually resolve the situation with patience and calm persuasion. A resolution may require the help of others, such as medical control or law enforcement officials. In most states, consent to treat a minor is required from only one parent or guardian.

If you are unable to obtain consent, then carefully document all your assessment findings, including the patient's history; the reasons for refusing emergency medical care; and all of the information provided to the patient, parent, or legal guardian. Note how much time you spent attempting to provide emergency medical care. Remember, the report and patient signature should be witnessed by an impartial observer. If the patient refuses to sign the release form, then the best you can do is inform your medical director and thoroughly document the situation and the refusal. Report to medical control and follow your local protocols with regard to this situation. Always advise the patient and family members to call 9-1-1 again for help if needed, and document this exchange on your PCR.

Street Smarts

If a patient refuses treatment and transport, but agrees to go to the hospital in a personal vehicle, then offer to assist the patient with getting into the vehicle to ensure the patient does seek medical care.

Advance Directives

Imagine that you and your partner respond to a call in which a patient is dying of an illness. When you arrive at the scene, you find that family members do not want you to try to resuscitate the patient.

Without valid written documentation from a physician, such as a **do not resuscitate (DNR) order** (also known as a do not attempt resuscitation order), this type of request places you in a difficult position. Recall that competent patients are able to make rational decisions about their well-being. An **advance directive** is usually a written document (but can also be a verbal statement) that specifies the desired medical treatment for a competent patient, should the person become unable to make decisions. An advance directive is also commonly called a living will, but may also be referred to as a **health care directive**. Advance directives specify what is to be done in specific situations and are most commonly used when a patient becomes comatose. Living wills, DNR orders, and organ donation orders are all examples of advance directives.

DNR orders give you permission not to attempt resuscitation. Although laws might differ from state to state, generally speaking, DNR orders must meet the following requirements to be valid:

- Clearly state the patient's medical condition(s)
- Signature of the patient or legal guardian
- Signature of one or more physicians (or other licensed health care providers)
- In some states, DNR orders contain expiration dates. DNR orders with expiration dates must be dated in the preceding 12 months to be valid.

However, even in the presence of a DNR order, you are still obligated to provide supportive measures (oxygen, pain relief, and comfort) to a patient who is not in cardiac or respiratory arrest, whenever possible. Each EMS agency, in consultation with its

Words of Wisdom

An advance directive specifically states what type of medical care the patient wishes to receive in a given situation—for example, the desire to have BLS performed, but no ALS procedures or equipment.

Words of Wisdom

DNR orders typically state that if the patient is apneic and pulseless, then no resuscitation measures are to be taken.

medical director and legal counsel, must develop a protocol to follow in these circumstances.

In the absence of an advance directive or DNR, some patients may have a **durable power of attorney for health care** or a **health care proxy**, a named surrogate to make decisions for them regarding their health care in the event they are incapacitated and unable to make decisions themselves. Many different types of powers of attorney exist, and not all authorize the exercise of medical decision making. Some powers of attorney simply authorize someone to handle the financial affairs of the person executing the power, and others will apply only if the person executing the power is still competent. Also, remember that a patient who remains responsive and competent has the right to make medical decisions; the person named in the power of attorney or health care proxy is only authorized to make decisions when the patient is no longer capable of doing so. When presented with a power of attorney at the scene of a medical emergency, read it carefully to ascertain its meaning and validity. If you have any questions, then contact online medical control for assistance. Do not delay emergency medical care while efforts to interpret the power of attorney are made.

You will care for patients in nursing homes, hospice programs, and home health programs.

Specific guidelines vary from state to state, but the following four statements may be considered general guidelines:

1. Patients have the right to refuse treatment, including resuscitation efforts, provided that they are able to communicate their wishes in a competent manner. Patients also have the right to withdraw a DNR for themselves and request emergency medical care.
2. A written order from a physician is required for DNR orders to be valid in a health care facility.
3. You should periodically review state and local protocols and legislation regarding advance directives.
4. If you are in doubt or the written orders are not present, then begin BLS and contact medical control for guidance.

If little chance of patient survival exists, then resuscitation is considered to be medically futile. Futile resuscitation efforts include situations where death is imminent, such as resuscitation efforts for patients who are terminally ill, life-sustaining interventions for patients in a persistent vegetative state, or use of chemotherapy in patients with cancer in advanced stages. This area is controversial because it often places the physician in opposition to the patient's family. The physician may feel that it is

YOU are the Provider

Part 3

Through effective communication, you are able to persuade your patient to agree to transport by ambulance. After securing your patient to the stretcher and initiating nonemergent transport to the hospital, you obtain the following vital signs.

Recording Time: 5 Minutes

Respirations	22 breaths/min; clear bilaterally
Pulse	Strong and irregular; 92 beats/min
Skin	Warm and dry
Blood pressure	146/92 mm Hg
Oxygen saturation (SpO₂)	96% on room air
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

5. Does this patient's irregular heart rate concern you?
6. Is any evidence of a head injury present?

unethical to provide futile treatment and give false hope, yet the family may not be ready to let go.

Physician Orders for Life-Sustaining Treatment

You may also encounter an end-of-life document that emerged in the early 1990s known as Physician Orders for Life-Sustaining Treatment (POLST). POLST is also known as Medical Orders for Life-Sustaining Treatment, Medical Orders on Scope of Treatment, and Physician's Orders on Scope of Treatment, depending on the state or geographic location. Although similar to a DNR in many respects, the POLST is more expansive and encourages physicians to speak with patients with a terminal illness and create specific medical orders to be followed at the end of life. It is intended to be followed by all health care providers, not just EMS personnel. A DNR generally applies to patients who are in cardiac arrest, whereas POLST may apply to patients with impending pulmonary failure who are not in cardiac arrest. POLST typically contains provisions that address the initiation of CPR, intubation, feeding tubes, the use of antibiotics, and comfort care or palliative care (intended to provide comfort and relief from pain during the dying process). POLST applies only when the patient has lost decision-making capacity. Be familiar with which documents are recognized in your state, and always contact medical control in complex situations involving resuscitation or end-of-life care.

Ethical Principles and Moral Obligations

In addition to legal duties, you have certain ethical responsibilities as a health care provider. These responsibilities are to yourself, your coworkers, the public, and the patient. As mentioned previously, ethics are related to action, conduct, motive, character, and responsibility. **Ethics** is the philosophy of right and wrong, of moral duties, and of ideal professional behavior. It is often referred to as the study of morality. **Morality** is a code of conduct that can be defined by society, religion, or a person, affecting character, conduct, and conscience. From an EMS standpoint, ethics are associated with what the EMS profession deems right or fitting conduct. An entire field of ethics known as **bioethics** has evolved over

the past several decades that addresses issues that arise in the practice of health care. Many such issues have drawn national attention, such as those dealing with the termination of life support, rationing of medical resources, and physician-assisted suicide. Ethical issues are present in nearly every EMS incident. Treating a patient ethically means doing so in a manner that conforms to professional standards of conduct and keeps the patient's best interests at the forefront of decision making. The manner in which principles of ethics are incorporated into professional conduct is known as **applied ethics**.

How can you make sure that you are acting ethically, especially with all the decisions you have to make in the field? **TABLE 3-1** lists guidelines to assist you in ethical decision making.

You must meet your legal and ethical responsibilities while caring for your patients' physical and

TABLE 3-1 Guidelines for Ethical Decision Making

1. Have you considered all options available to you and the consequence of each option?
2. What decisions have been made regarding a similar situation? Is this a type of problem that reflects a rule or policy? Can an existing policy or rule be applied? This guideline uses the concept of **precedence**, defined as basing current action on lessons, rules, or guidelines derived from previous similar experiences.
3. How would this action affect you if you were in your patient's position, or the family's position? What action is in the patient's best interest?
4. Would you feel comfortable having all prehospital care providers apply this action in all similar circumstances?
5. Can you justify your action(s) to:
 - Your peers?
 - The public?
 - Your supervisor?
 - Your medical director?
6. How will the consequences of your decision provide the greatest benefit in view of all of the alternatives?
7. Have you involved online medical control in your decision making?

emotional needs. Patient needs vary depending on the situation. In most cases, an existing rule, law, or policy will guide your decision making and your actions. As a professional, you are bound to follow all such rules, laws, and policies, even in those rare circumstances where your own personal sense of ethics might lead you to a different result.

One unquestionable responsibility you have is honest reporting. Absolute honesty in reporting is essential. You must provide a complete account of the events and the details of all patient care and professional duties. Accurate records are also important for quality improvement activities.

To provide the best level of emergency medical care, it is necessary to maintain mastery of skills. Participating in continuing education and refresher training not only provides updates on changes and new procedures in EMS, but also keeps you current in the areas that are dealt with infrequently (such as obstetrics and pediatrics). As an AEMT, you have a moral obligation to make sure that you are knowledgeable in all areas of emergency medical care to ensure that you care for patients to the best of your ability. Critically reviewing your performance and seeking improvement are ethical concerns.

Ethical conflicts may arise during your work as an AEMT, causing distress. As mentioned previously, medical futility becomes an issue when faced with a situation in which attempts to provide life support may be futile due to location. An example would be the case of a cardiac arrest in the wilderness in which time to definitive care makes prolonged attempts at resuscitation futile. Allocation of resources becomes an ethical decision-making process in the event of a triage situation in which the demand for emergency medical care exceeds your resources. Recall that triage is the practice of doing the most good for the greatest number of patients. This practice means making the decision to leave patients who, under other circumstances, may have been viable. Professional misconduct presents yet another conflict when evidence of patient abuse by EMS professionals exists. Finally, consider the practice of economic triage or patient dumping, where patients are left because they may not generate as much income as another or a patient is denied medical treatment because of the inability to pay.

Failure to meet legal or ethical standards may result in you being charged civilly, criminally, or both. The best legal protection is performing an appropriate

Words of Wisdom

Regardless of the ethical circumstances you may encounter, you should always apply three basic ethical concepts, considered an inherent part of health care for centuries, when making a decision:

1. Do no harm.
2. Act in good faith.
3. Always act in the patient's best interest.

assessment and providing emergency medical care that is safe, effective, and competent, coupled with accurate and complete documentation. Laws differ from state to state and area to area, so be sure to seek legal advice if needed. By staying up-to-date on skills and information and treating patients with the same consideration and respect that you would give one of your close family members, you may limit possible complications that can have legal ramifications.

Confidentiality

Communication between you and the patient is considered confidential and generally cannot be disclosed without permission from the patient or a court order. Confidential information includes the patient history, assessment findings, and treatment provided. You cannot disclose information regarding a patient's diagnosis, treatment, or mental or physical condition without consent; if you do, you may find yourself liable for **breach of confidentiality**. In certain situations, you may release confidential information to designated people. In most states, patient records may be released when a legal subpoena is presented or the patient signs a written release form. The patient must be mentally competent and fully understand the nature of the release. In some situations, confidential information may be released for other purposes, which are not considered a breach of confidentiality. These situations include sharing patient information with third-party billing personnel, disclosure to state or local health agencies concerning certain diseases that may affect a population, and events such as seizure activity that may be reported to the Department of Motor Vehicles. In many states, you do not need a written release to report information about cases of rape or abuse to proper authorities.

Another means for disclosing confidential information is through automatic release, which does not require a written form. This type of release allows you to share information with other health care providers so that they may continue the patient's care.

Improper release of confidential information or release of inaccurate information can result in liability. *Invasion of privacy* is the release, without legal justification, of information about a patient's private life that might reasonably expose the patient to ridicule, notoriety, or embarrassment. The fact that the information is true is not a defense. These statements, whether verbal or written, are made with malicious intent or reckless disregard for the accuracy of the statements. Breaches of confidentiality may also result in charges of libel or slander.

To protect yourself, be sure to document only objective findings and omit personal opinions. Do not give information to anyone other than other health care professionals directly involved in the patient's continuing care. Briefly, but politely, explain to others such as family members and concerned friends that you cannot give out information regarding the patient's condition. Instead, suggest that they follow up with immediate family members after the patient has been seen in the ED.

Health Insurance Portability and Accountability Act

The **Health Insurance Portability and Accountability Act (HIPAA)**, enacted in 1996, provides for criminal sanctions as well as civil penalties for releasing a patient's confidential medical information in an unauthorized manner. Although this act had many aims, including improving the portability and continuity of health insurance coverage and combating waste and fraud in health insurance and the provision of health care, the section of the act that most affects EMS relates to patient privacy. The aim of the HIPAA Privacy Rule was to strengthen laws for the protection of the privacy of health care information and to safeguard patient confidentiality. As such, it provides guidance on what types of information are protected, the responsibility of health care providers regarding that protection, and penalties for breaching that protection. Medical information can be disclosed only if it is necessary for a patient's treatment, billing, or operations. As mentioned previously, this practice means you are permitted to

report your assessment findings and treatment to other health care providers directly involved in the care of the patient. You may also release medical information for third-party billing.

HIPAA considers all patient information that you obtain in the course of providing medical treatment to a patient to be **protected health information (PHI)**. This PHI includes not only medical information, but also any information that can be used to identify the patient. As an AEMT, you have an obligation to safeguard all PHI from unlawful disclosure, either written or verbal. Safeguards to protect this information include departmental security measures to prevent HIPAA violations, such as rules to prohibit sharing of passwords or log-in credentials to systems that contain PHI; proper measures to dispose of documents or other records that contain PHI; and rules to never leave electronic devices or patient reports that contain PHI unattended. PHI must also be maintained when two or more patients, who may or may not be family, are close to each other, such as in the back of an ambulance.

If you are unsure, then do not give any information to anyone other than those directly involved in the care of the patient. For specific policies, each EMS agency is required to have a manual and a designated privacy officer who can answer questions. You can expect to receive additional training on how HIPAA has an effect on your specific response agency.

It cannot be overstated that any sharing of private or protected information, whether it is directly sharing images or recordings or verbally relaying information, is a serious violation of HIPAA and ethical principles, even when done privately. In situations where responders or care providers casually share information, such as in face-to-face conversations at the station or in social media postings, the communications may feel private. However, private and protected information must remain between the patient and the caregiver only. Information about emergency calls may be used under special circumstances for purposes such as education and quality improvement, but all identifying and private information must first be removed.

The general public is often permitted by law to record identifying and protected patient information and images. For example, while it would be unethical and illegal for a responding AEMT to take a picture of a severely injured patient while caring for the person at a motor vehicle collision, if the

collision takes place on a public road and in public view, members of the general public can, and often will, record the incident. In most of these situations, AEMTs, and even law enforcement officers, cannot order members of the public to stop recording, confiscate their phones or cameras, or otherwise interfere with the public.

Street Smarts

Often a polite request made to members of the public to respect patient privacy is sufficient to stop them from filming or photographing at public scenes.

Social Media

Although unauthorized sharing of private and protected patient information is never permitted, sharing personal opinions about work and non-work-related topics via social media is a complex and controversial topic. Whether such sharing is appropriate depends greatly on the nature of the information and the circumstances (eg, who is sharing it, how, when, and where?).

In general, if an AEMT uses agency-supplied equipment to record or distribute information, or records or distributes information while in the course of their duties (including volunteering), the agency likely owns the images and information. In many states, the agency must follow requirements to control and store this content and, in some cases, release it to the public on request. Moreover, if AEMTs associate themselves with their agency, such as showing a logo, wearing their uniform, or specifically identifying their agency, they may not be able to express their private views in the same way that other members of the general public could. There are no absolute recommendations when it comes to social media, but the following advice may help keep AEMTs away from serious ethical or legal issues:

- Unless you are operating as an official spokesperson for your agency, avoid logos, uniforms, vehicles, or other markings that associate you with your agency while off duty.
- Conduct yourself online with the same professionalism that you do while on duty.
- Respect your patients, their friends and family, bystanders, colleagues, and the organization for which you work both in person and online.

- Recognize that free speech does not mean every person has a right to say anything under any circumstances and without repercussions.

Records and Reports

Certain people and agencies, such as the EMS system, are in a position to obtain information about diseases, injuries, and emergency events, and they may be required by statute or regulation to compile the information and report it to regulatory or accreditation agencies. Even if no such requirement exists, you should compile a complete and accurate record of all incidents in which you come in contact with sick or injured patients. A complete and accurate record of an emergency medical incident is an important safeguard against legal action. The absence of a record or a substantially incomplete record may mean that you might have to testify about the events, your findings, and your actions by relying on memory alone, which can prove to be inadequate and embarrassing in the face of aggressive cross-examination.

The courts often consider the following two rules of thumb regarding reports and records:

- If an action or procedure is not recorded on the written report, then it was not performed.
- An incomplete or untidy report is evidence of incomplete or inexperienced emergency medical care.

You can avoid both of these potentially dangerous presumptions by compiling and maintaining accurate PCRs and records of all events and patients. PCRs also help the EMS system evaluate individual and service provider performance. PCRs are an integral part of most quality assurance programs. Data extraction from PCRs is also used to conduct prehospital emergency care research, which may improve patient outcomes.

The National EMS Information System (NEMSIS) is a tool for the EMS profession. NEMSIS provides the ability to collect, store, share, and analyze standardized EMS data throughout the United States. This useful database can be used to improve the speed and accuracy of data collection. NEMSIS could, for example, provide early warning of a disease outbreak. Although almost all US states and territories report EMS events to NEMSIS, the objective is for all EMS agencies to ensure full compliance with the system.⁴

Words of Wisdom

Ensure your documentation is accurate and thorough. If the care you provided is ever called into question during a legal proceeding, your documentation will help you remember the details of the call and demonstrate your credibility and professionalism to the court.

Mandatory Reporting Requirements

All states and the District of Columbia have enacted laws to protect children who have been abused, and some have added other protected groups such as the older population and at-risk adults. Most states have a reporting obligation for certain people, ranging from physicians to any person. Be aware of the requirements of the law in your state. Failure to report child abuse or neglect is usually classified as a misdemeanor and may result in a fine or imprisonment, and in subsequent cases, it may become a felony. Failure to report most of the situations listed here may result in disciplinary action, suspension of your privileges to practice as an AEMT, a fine, and even criminal prosecution.

The obligation to report is most frequently applied to the following categories of cases:

- Neglect or abuse of children
- Neglect or abuse of older people

- Domestic violence
- Injury sustained during the commission of a felony or specific injuries considered to be of suspicious origin (such as gunshot wounds or stab wounds)
- Drug-related injuries
- Childbirth occurring outside a licensed medical facility
- Rape
- Animal bites
- Certain communicable diseases

As noted, reporting requirements vary widely from state to state. Learn the laws of your state and observe the reporting obligations that apply to you.

Scene of a Crime

If evidence is present at an emergency scene that indicates a crime may have been committed, then notify the dispatcher immediately so that law enforcement authorities can respond. Such circumstances should not stop you from providing necessary emergency medical care to the patient; however, your safety is a priority, so first ensure that the scene is safe to enter. If the patient shows signs of obvious death (such as decapitation), then take necessary precautions not to disturb the crime scene because this may interfere with the subsequent investigation.

YOU are the Provider**Part 4**

Per your protocols, any patient being transported to the ED with a possible head injury requires IV access. As you prepare your equipment, the patient looks at you and states, "I do not like needles, and I do not want an IV line."

Recording Time: 12 Minutes

Respirations	21 breaths/min; clear bilaterally
Pulse	Strong and irregular; 87 beats/min
Skin	Warm and dry
Blood pressure	142/88 mm Hg
Oxygen saturation (SpO₂)	96% on room air
Pupils	PERRLA

7. Because your protocols state that all patients with possible head injuries require an IV line, can you force the patient to receive one?
8. What are the possible consequences of placing an IV line in this patient against his wishes?

Special Populations

EMS personnel are often the best source to recognize abuse or neglect of those patients unable to speak for themselves. It is your responsibility to be an advocate for these populations when the need arises. Always look for injuries that are inconsistent with explanations, as well as other signs of abuse or neglect. Always report suspicious behavior, suspicious circumstances, or poor living conditions to the appropriate authorities for investigation. Removing a patient from an unhealthy environment may be the best course of action; however, this step may require convincing a caregiver to allow that patient to be transported. Remain professional and explain the need for treatment and transport based on physical findings.

Words of Wisdom

When you obtain the medical history from a patient you suspect has been abused, you may get more accurate information if your partner interviews the parents or other caregivers separately. Patients who have been abused may be reluctant to speak openly in front of their abusers.

At times, you may have to transport the patient to the hospital before the authorities arrive. While you provide emergency medical care, be careful not to disturb the scene of the crime any more than absolutely necessary. Make notes and drawings of the position of the patient and of the presence and position of any weapon or other objects that may be valuable to the investigating officers. If possible, do not cut through holes in clothing from knife or gunshot wounds. Confer periodically with local authorities and be aware of the actions they want you to take at the scene of a crime. It is best if these guidelines can be established by protocol.

The Deceased

In most states, while AEMTs may have the authority to terminate resuscitation efforts or to elect not to initiate resuscitation efforts in specific circumstances, they still do not have the specific authority to pronounce a patient dead. If there is any chance that life exists or that the patient can be resuscitated, then initiate resuscitation efforts at the scene and during transport. However, when death is obvious, no urgent reason exists to move the body.

The only immediate action that is required of you is to cover the body and prevent its disturbance. Local protocol will determine your ultimate action in these instances.

Physical Signs of Death

Determination of the cause of death is the medical responsibility of a physician. There are both definitive and presumptive signs of death. In many states, death is defined as the absence of circulatory and respiratory function. Many states have also adopted brain death provisions; these provisions refer to irreversible cessation of all functions of the brain and brainstem. Questions often arise as to whether to begin BLS. In the absence of physician orders such as DNR orders, the general rule is as follows: if the body is still intact and no definitive signs of death are present, then initiate emergency medical care. An exception to this rule is cold temperature (hypothermia) emergencies. Hypothermia is a general cooling of the body in which the core body temperature becomes abnormally low: 95°F (35°C). It is a serious condition and is often fatal. At 86°F (30°C), the brain can survive without perfusion for about 10 minutes. When the core body temperature drops to 82.4°F (28°C), the patient is in grave danger; however, people have survived a hypothermia incident with a body temperature of 64°F (18°C). In cases of hypothermia, patients should not be considered dead until they are warm and dead. If the patient's condition is unclear, or if you are unsure whether to initiate care, then it is best to begin CPR immediately and contact medical control for guidance. Remember, not all incidents of hypothermia occur outdoors; for example, an older patient in a home without heat or who has been lying on a cold floor could have hypothermia.

Words of Wisdom

Clinical death is the absence of respirations and a pulse. *Biologic death* begins within 4 to 6 minutes of clinical death as cells start to die. This process can be slowed in cold environments.

Presumptive Signs of Death

Most medicolegal authorities will consider the presumptive signs of death that are listed in **TABLE 3-2** adequate, particularly when the signs follow a severe

TABLE 3-2 Presumptive Signs of Death

- Unresponsiveness to painful stimuli
- Lack of a carotid pulse or heartbeat
- Absence of chest rise and fall
- No deep tendon or corneal reflexes
- Absence of pupillary reactivity
- No systolic blood pressure
- Profound cyanosis
- Lowered or decreased body temperature

© Jones & Bartlett Learning.

trauma or occur at the end stages of a long-term illness such as cancer. These signs alone would not be adequate in cases of sudden death as a result of hypothermia, acute poisoning, or cardiac arrest. Usually, in these cases, some combination of the presumptive signs is needed to declare death, not only one of them.

Definitive Signs of Death

Definitive or conclusive signs of death that are obvious and clear to even nonmedical people include the following:

- Obvious mortal damage, such as dismemberment at the waist or neck (decapitation)
- **Dependent lividity:** Blood settling to the lowest point of the body, causing discoloration of the skin (**FIGURE 3-8**)
- **Rigor mortis:** The stiffening of body muscles caused by chemical changes within muscle tissue. It develops first in the face and jaw, gradually extending downward until the body is in full rigor. The rate of onset is affected by the body's loss of heat to its surroundings. A thin person experiences heat loss faster than a person with obesity. A person on a tile floor experiences heat loss faster than a person wrapped up in a blanket in a bed. Rigor mortis occurs sometime between 2 and 12 hours after death.
- **Putrefaction:** The decomposition of body tissues. Depending on temperature conditions, this sign occurs sometime between 40 and 96 hours after death.

FIGURE 3-8 Dependent lividity is an obvious sign of death caused by discoloration of the body from pooling of the blood to the lower parts of the body.

© American Academy of Orthopaedic Surgeons.

FIGURE 3-9 When trauma is a factor or the death involves an unusual or suspected criminal situation, the medical examiner is required to investigate.

© Jack Dagley Photography/Shutterstock.

Coroner and Medical Examiner Cases

Involvement of the medical examiner, or the coroner in some states, depends on the nature and scene of the death. In most states, when trauma is a factor or the death involves suspected criminal or unusual situations such as hanging or poisoning, the medical examiner must be notified (**FIGURE 3-9**). When the medical examiner or coroner assumes responsibility for the scene, that responsibility supersedes

all others at the scene, including that of the family's. The following are a few examples of deaths that may be considered medical examiner cases:

- When the person is dead on arrival
- Death without previous medical care or when the physician is unable to state the cause of death
- Suicide (self-destruction)
- Violent death
- Poisoning, known or suspected
- Death resulting from accidents
- Suspicion of a criminal act
- Death of an infant or child

As mentioned previously, make every attempt to limit your disturbance of a scene involving a death. After you have adequately determined death based on local protocols, remove yourself from the scene. This practice is especially important if the cause of death is potentially suspicious.

If emergency medical care has been initiated, then keep thorough notes of what was done or found. These records may be important during a subsequent investigation. These records should include the position in which the patient was found; any weapons, medication bottles, or other important objects; and anything else relating to the scene that you witnessed.

Special Situations

Organ Donors

You may be called to a scene involving a potential organ donor, a person who has expressed a wish to donate organs. Consent to organ donation is voluntary and informed. Consent is evidenced by either a donor card or a driver's license indicating that the person wants to be a donor (**FIGURE 3-10**). You may need to consult with medical control when you encounter this situation.

In specific circumstances, a patient who is not successfully resuscitated may be a potential organ donor. Certain centers can procure organs, including the kidneys and liver, in certain situations. These situations typically occur after in-hospital cardiac arrest, but may be associated with certain specific out-of-hospital cardiac arrest situations that occur in close proximity to specialized centers. Be aware of your local centers and the respective protocols and capabilities.

Organ/Tissue Donor Card

I wish to donate my organs and tissues. I wish to give:

☐ any needed organs and tissues ☐ only the following organs and tissues:

Donor Signature _____ Date _____
 Witness _____
 Witness _____

FIGURE 3-10 Patients may be carrying a donor card or driver's license indicating that they wish to be an organ donor.

Courtesy of the US Department of Health and Human Services.

FIGURE 3-11 The patient may carry a medical identification card or wear a bracelet or necklace that indicates important medical information and a possible do not resuscitate order. In the case of a MedicAlert bracelet, the EMS provider can obtain stored patient information from the MedicAlert Foundation.

Courtesy of the MedicAlert Foundation®. © 2006, All Rights Reserved. MedicAlert® is a federally registered trademark and service mark.

Treat a potential organ donor in the same way that you would treat any other patient. The fact that a patient is a possible donor does not mean that you should not use all means necessary to keep that patient alive. Organs that are often donated, such as a kidney, heart, or liver, need oxygen at all times; you must give the possible donor oxygen, or the organs will be damaged and become useless.

Remember that your priority is to save the patient's life. Learn the specific protocols in your area for these situations.

Medical Identification Insignia

Many patients will carry important medical identification and information, often in the form of a bracelet, necklace, keychain, or wallet card (**FIGURE 3-11**). This patient history information may include a DNR

order or specify whether the patient has allergies, diabetes, epilepsy, or some other serious condition. This information is helpful to you in assessing and treating the patient. Be sure to check any jewelry

that the patient may be wearing because identification comes in many different forms. Some patients wear medical bracelets with USB flash drives that contain important medical information.

YOU are the Provider **SUMMARY**

1. Can this patient refuse treatment when it is obvious that he needs stitches?

This patient is fully within his rights to refuse treatment because he is alert and oriented, and competent to refuse treatment (not under the influence of mind-altering substances). The fact that he requires stitches does not in any way eliminate or even limit any of his rights to patient autonomy.

2. What can you and your partner do to attempt to persuade this patient to consent to treatment and transport?

Calmly and clearly explain to the patient that his condition requires treatment that you are currently unable to provide. Further explain to the patient the potential risks of not obtaining treatment, as well as the complications of not seeking immediate treatment.

3. What concerns do you have regarding the patient's mechanism of injury?

It is obvious, both by visual clues and the patient's own explanation, that he struck his head on a table. Because of this evidence, the potential for a closed head injury exists. However, the patient is showing no signs of a head injury and is able to recount all of the events prior to and after the incident—minimizing, but not totally removing, the possibility of a head injury.

4. What alternative options do you have regarding transport to the ED?

Because this patient does not want to go to the hospital in an ambulance, it may be possible to persuade the patient to go to the hospital by alternative means, such as a taxi or in the personal vehicle of a friend or family member. If possible, and if the patient agrees to alternate transportation, then attempt to secure another means of transportation for him.

Note, the patient must understand that you are not recommending taxi transport in lieu of ambulance transport. You are simply helping him receive care in the context of his informed desire to avoid the cost of ambulance transport. You may help him

arrange a taxi, but that help should be delivered with a clear understanding that you are offering him ambulance transport to the hospital and not recommending a different means. Never talk a patient into an alternative to hospital transport. If any such allegation can be made against you, you could be held liable for any adverse outcome related to deterioration in the patient's condition during the taxi ride. For example, this patient could lose consciousness and die on the way to the hospital while alone in the back of a taxi, and his relatives could sue you for negligence and abandonment if it is later determined that you advised him to use a taxi to go to the hospital instead of an ambulance. If he refuses care after clearly being informed of the risks, document the conversation honestly, thoroughly, and carefully. Remember, the amount of documentation necessary to support an informed refusal is far greater than the amount of documentation necessary to record the events associated with an uneventful transport to the hospital.

5. Does this patient's irregular heart rate concern you?

It may. However, your level of concern depends on the history that the patient is able to provide to you. Does this patient have a history of an irregular heart-beat? Was he feeling any heart palpitations prior to falling? Did he experience any other abnormal feeling prior to falling? If, after careful questioning, the patient's history points to a new primary cardiac event, then strongly urge ambulance transport so that cardiac monitoring may be initiated en route to the ED. Medical emergencies will be covered fully in later chapters.

6. Is any evidence of a head injury present?

No evidence of a head injury is present, other than the laceration to the forehead. The patient does not exhibit any signs of Cushing triad (hypertension, bradycardia, or abnormal respiratory pattern), and although an underlying problem that you cannot see may exist, the patient is not experiencing any of the classic signs or symptoms of a head injury. You will

YOU are the Provider SUMMARY *continued*

learn about Cushing triad in Chapter 19, *Neurologic Emergencies*.

7. Because your protocols state that all patients with possible head injuries require an IV line, can you force the patient to receive one?

No. As long as the patient is alert and oriented, and competent to refuse treatment, the patient has the right to refuse any portion of treatment.

8. What are the possible consequences of placing an IV line in this patient against his wishes?

The possible consequences of placing an IV line in a patient who has stated that he does not want one are charges of assault and battery. The patient has stated that he does not like needles, and by threatening him with an IV line, you could be found guilty of assault. Battery is unlawfully touching a person, as in the case of physically starting the IV line.

EMS Patient Care Report (PCR)

Date: 12-16-20	Incident No.: 20090508431	Nature of Call: Fall		Location: 176 South Cavalier St	
Dispatched: 1825	En Route: 1828	At Scene: 1832	Transport: 1854	At Hospital: 1902	In Service: 1915
Patient Information					
Age: 84 Sex: M Weight (in kg [lb]): 57 kg (125.4 lb)			Allergies: No known drug allergies Medications: Coumadin Past Medical History: Irregular heartbeat Chief Complaint: Head laceration		
Vital Signs					
Time: 1837	BP: 146/92	Pulse: 92, Irregular	Respirations: 22	SpO₂: 96%	
Time: 1844	BP: 142/88	Pulse: 87, Irregular	Respirations: 21	SpO₂: 96%

EMS Treatment (highlight all that apply)					
Oxygen @ _____ L/min via (circle one): NC NRM Bag-mask device		Assisted Ventilation	Airway Adjunct	CPR	
Defibrillation	Bleeding Control	Bandaging	Splinting	Other:	
Narrative					

EMS called to above location for a man who fell. On arrival, met by above patient with an obvious laceration to his forehead approximately 1 inch (2.5 cm) in length, jagged in appearance. Patient states he was walking to the sofa and tripped over a lamp cord. Patient states that he struck his head on the corner of the coffee table, but denies a loss of consciousness or any pain. Bleeding stopped spontaneously. Advised patient of the need to be transported to the ED for possible stitches. Patient states that he does not want to go to the hospital via ambulance because he cannot afford the bill because he is on a fixed income. Reiterated to the patient the need for evaluation at the ED. Patient reluctantly consented for treatment and transport. Assisted the patient to the stretcher, where he was secured, and transported nonemergent to Marias Medical Center. En route—vital signs obtained. Pulse noted to be irregular; however, patient states that he has a history of atrial fibrillation and that an irregular heartbeat was normal for him. While setting up equipment for IV line insertion, patient stated that he did not want an IV line because he does not like needles. Informed the patient of the purpose for the IV line, and the risks and consequences of refusing such treatment. Patient verbalized understanding of the risks and benefits, and still refused. Report called to ED with condition and ETA. On arrival, care and report given to RN without incident.

End of report

Prep Kit

Ready for Review

- The scope of practice outlines the emergency medical care you are able to provide to the patient and is most commonly defined by law. The medical director further defines the scope of practice.
- Standards of care are established in many ways, among them local customs, statutes, ordinances, protocols, textbooks, administrative regulations, and case law.
- Determination of negligence is based on the following four factors: (1) duty, (2) breach of duty, (3) damages, and (4) proximate cause. All four elements must be present for the legal doctrine of negligence to apply and for a plaintiff to prevail in a lawsuit against an EMS system or provider.
- After your ambulance responds to a call or treatment is begun, you have a legal duty to act. In most cases, if you are off duty and encounter a motor vehicle crash, you are not legally obligated to stop and assist patients.
- Abandonment is the termination of emergency medical care without the patient's consent and without making provisions for the transfer of care to a health care professional with skills at the same level or a higher level than yours. Abandonment is a legally and ethically serious matter that exposes the patient to harm and can result in civil action against you. Always try to obtain a signature on your PCR from the person accepting transfer of care.
- To protect yourself from charges of assault, battery, kidnapping, or false imprisonment, be sure to obtain expressed consent whenever possible.
- Defamation is intentionally making a false statement through written communication (libel) or verbal communication (slander) that injures a person's good name. Only communicate information about your patients to authorized people, and ensure that the information contained in your PCRs and other documentation is accurate and relevant.
- Good Samaritan laws are based on the common law principle that when you reasonably help another person, you should not be liable for errors and omissions that are made in giving good faith emergency care. Whereas some laws provide Good Samaritan protection for anyone who stops to render aid during an emergency, others only provide protection for those with no medical training.
- Under most circumstances, you are required to obtain consent from every responsive adult before starting emergency medical care. The foundation of consent is decision-making capacity. To protect yourself from legal action, be sure to obtain expressed consent (either verbal or nonverbal) whenever possible.
- When a patient is unresponsive and unable to give consent, the law assumes implied consent (also known as the emergency doctrine); therefore, you should proceed with treatment.
- Never withhold life-saving emergency medical care unless a valid do not resuscitate order or advance directive is present.
- Try to obtain consent from a parent or legal guardian of a minor (younger than age 18 years in most states) whenever possible. Again, never withhold life-saving emergency medical care.
- Mentally competent patients have the right to refuse treatment. In these instances, have the patient sign a refusal form, and make sure your department keeps a copy.
- Advance directives, living wills, or health care directives are most commonly used when a patient becomes comatose.
- As an AEMT, you have ethical responsibilities. Treating a patient ethically means doing so in a manner that conforms to professional standards of conduct and keeps the patient's best interests at the forefront of decision making.
- Communication between you and the patient is confidential; do not disclose private medical information without permission from the patient or a court order. In some situations, confidential information may be released for other

purposes, which include sharing patient information with third-party billing personnel.

- Records and reports are important; ensure that you compile a complete and accurate record of each incident. You may need to testify about certain events, and the courts often consider the following two rules of thumb:
 - If an action or procedure is not recorded on the written report, then it was not performed.
 - An incomplete or untidy report is evidence of incomplete or inexperienced emergency medical care.
- Understand the mandatory reporting requirements involving abuse or neglect of children, older adults, and other at-risk populations; injuries related to crimes; drug-related injuries;

and childbirths occurring outside a licensed medical facility.

- There are both definitive and presumptive signs of death. In many states, death is defined as the absence of circulatory and respiratory function. Many states have also adopted “brain death” provisions; these provisions refer to irreversible cessation of all functions of the brain and brainstem.
- Be sure to note whether the patient is carrying some type of medical identification information (eg, in the form of a bracelet, necklace, keychain, or wallet card). If you fail to take this information into account, then you may harm the patient.

Vital Vocabulary

abandonment Unilateral termination of emergency medical care by the AEMT without the patient’s consent and without making provisions for transferring care to another medical professional with the skills and training necessary to meet the patient’s needs.

advance directive Written documentation that specifies medical treatment for a competent patient should the patient become unable to make decisions; also see *health care directive*.

applied ethics The manner in which principles of ethics are incorporated into professional conduct.

assault Unlawfully placing a patient in fear of immediate bodily harm.

battery Unlawfully touching a patient or providing emergency medical care without consent.

bioethics The study of ethics related to issues that arise in health care.

breach of confidentiality Disclosure of medical information without proper authorization.

breach of duty Occurs when a person accused of negligence fails to act as another person with similar training would act under the same or similar circumstances.

certification A process in which a person, an institution, or a program is evaluated and

recognized as meeting certain predetermined standards to provide safe and ethical patient care.

civil lawsuit An action instituted by a person or entity against another person or entity.

compensatory damages Compensation awarded in a civil lawsuit that is intended to restore the plaintiff to the same condition that the person was in prior to the incident.

competent Able to make rational decisions about personal well-being.

consent Permission to render emergency medical care.

credentialing An established process to determine the qualifications necessary to be allowed to practice a particular profession, or to function as an organization.

criminal prosecution An action instituted by the government against a person for violation of criminal law.

damages Compensation for injury; awarded by a court.

decision-making capacity The ability to understand and process information and make a choice regarding appropriate medical care.

defamation The communication of false information about a person that is damaging

to that person's reputation or standing in the community.

defendant In a civil lawsuit, the person against whom a legal action is brought.

dependent lividity Blood settling to the lowest point of the body, causing discoloration of the skin; a definitive sign of death.

depositions Verbal statements from parties and witnesses taken under oath.

discovery The phase of a civil lawsuit where the plaintiff and defense obtain information from each other that will enable the attorneys to have a better understanding of the case and that will assist them in negotiating a possible settlement or in preparing for trial; includes depositions, interrogatories, and demands for production of records.

do not resuscitate (DNR) order Written documentation by a physician giving permission to medical personnel not to attempt resuscitation in the event of cardiac arrest.

durable power of attorney for health care A type of advance directive executed by a competent adult that appoints another individual to make medical treatment decisions on the person's behalf in the event that the person making the appointment has a loss of decision-making capacity; also see *health care proxy*.

duty A medicolegal term relating to certain personnel who either by statute or by function have a responsibility to provide patient care.

emancipated minor A person who is under the legal age in a given state (age 18 years in most cases) but, because of other circumstances, is legally considered an adult.

emergency A serious situation, such as injury or illness, that threatens the life or welfare of a person or group of people and requires immediate intervention.

emergency doctrine The principle of law that permits a health care provider to treat a patient in an emergency situation when the patient is incapable of granting consent because the person is unresponsive, delusional, exhibiting an altered mental status as a result of drug or alcohol use, or is otherwise physically unable to give expressed consent; also see *implied consent*.

emergency medical care Immediate care or treatment.

Emergency Medical Treatment and Active Labor Act (EMTALA) A federal law enacted to combat the practice of patient dumping and that pays particular attention to the practice of sending women in labor to distant hospitals; prevents emergency department staff from denying medical screening or stabilizing treatment, or inappropriately transferring a patient whose condition is not stable to another hospital.

ethics The philosophy of right and wrong, of moral duties, and of ideal professional behavior.

expressed consent A type of consent in which a patient gives verbal or nonverbal authorization for provision of emergency medical care or transport.

false imprisonment The confinement of a person without legal authority or the person's consent that lasts for an appreciable period.

forcible restraint The act of physically subduing a patient to prevent harm.

Good Samaritan laws Statutory provisions enacted by many states to protect citizens from liability for errors and omissions in giving good faith emergency medical care, unless there is wanton, gross, or willful negligence.

governmental immunity Legal doctrine that can protect an emergency medical services provider from being sued or that may limit the amount of the monetary judgment that the plaintiff may recover; generally applies only to emergency medical services systems that are operated by municipalities or other government entities.

gross negligence Conduct that constitutes a willful or reckless disregard for a duty or standard of care.

health care directive A written document that specifies medical treatment for a competent patient, should the person become unable to make decisions; also see *advance directive*.

health care proxy A type of advance directive executed by a competent adult that appoints another individual to make medical treatment decisions on the person's behalf in the event that the person making the appointment loses

decision-making capacity; also see *durable power of attorney for health care*.

Health Insurance Portability and Accountability Act (HIPAA)

The law enacted in 1996 that provides for criminal sanctions as well as for civil penalties for releasing a patient's protected health information in a way not authorized by the patient.

immunity In medicine, the body's ability to protect itself from acquiring a disease; in a legal context, legal protection from penalties that could normally be incurred under the law.

implied consent A type of consent in which a patient who is unable to give consent (because the person is unresponsive, delusional, exhibiting an altered mental status as a result of drug or alcohol use, or is otherwise physically unable to give expressed consent) is given treatment under the legal assumption that the person would want treatment; also see *emergency doctrine*.

informed consent Permission for treatment given by a competent patient after the potential risks, benefits, and alternatives to treatment have been explained.

in loco parentis Latin phrase meaning "in the place of the parent" that refers to the legal responsibility of a person or organization to take on some of the functions and responsibilities of a parent or legal guardian on the behalf of a minor.

interrogatories Written questions that the defense and plaintiff send to one other.

kidnapping The seizing, confining, abducting, or carrying away of a person by force, including transporting a competent adult for medical treatment without the person's consent.

libel False and damaging information about a person that is communicated in writing.

licensure The process whereby a competent authority, usually the state, allows people to perform a regulated job, trade, or profession.

malfeasance An unauthorized act committed outside the scope of medical practice as defined by law.

medicolegal A term relating to medical jurisprudence (law) or forensic medicine.

misfeasance Appropriate act performed in an improper manner, such as a medication administered at the wrong dose.

morality A code of conduct that can be defined by society, religion, or a person, affecting character, conduct, and conscience.

negligence Failure to provide the same care that a person with similar training would provide.

negligence per se A theory that may be used when the conduct of the person being sued is alleged to have occurred in clear violation of a statute.

nonfeasance Failure to perform a required or expected act.

patient autonomy The right of a patient to make informed choices regarding their health care.

plaintiff In a civil lawsuit, the person who brings a legal action against another person.

precedence Basing current action on lessons, rules, or guidelines derived from previous similar experiences.

protected health information (PHI) Any information about health status, provision of health care, or payment for health care that can be linked to an individual. This information is interpreted rather broadly and includes any part of a patient's medical record or payment history.

protocols Precise and detailed plans for a regimen of therapy (for example, advanced cardiac life support algorithms).

proximate cause The specific reason that an injury occurred; one of the items that must be proven in order for an advanced emergency medical technician to be held liable for negligence.

punitive damages Compensation that is sometimes awarded in a civil lawsuit when the conduct of the defendant was intentional or constituted a reckless disregard for the safety of the public.

putrefaction Decomposition of body tissues; a definitive sign of death.

res ipsa loquitur Theory of negligence that assumes an injury can only occur when a negligent act occurs.

rigor mortis Stiffening of the body muscles caused by chemical changes within muscle tissue; a definitive sign of death.

scope of practice Most commonly defined by state law; outlines the emergency medical care that the advanced emergency medical technician is able to provide to the patient.

slander False and damaging information about a person that is communicated by the spoken word.

standard of care Written, accepted levels of emergency medical care expected by reason of

training and profession; written by legal or professional organizations so that patients are not exposed to unreasonable risk or harm.

standing orders Written documents, signed by the EMS system's medical director, that outline specific directions, permissions, and sometimes prohibitions regarding patient care; also called protocols.

statute of limitations The number of years after an incident during which a lawsuit can be filed.

tort A wrongful act that gives rise to a civil lawsuit.

Chapter 4

Communications and Documentation

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Preparatory

Applies fundamental knowledge of the EMS system, safety/well-being of the advanced emergency medical technician (AEMT), medical/legal, and ethical issues to the provision of emergency care.

Therapeutic Communication

Principles of communicating with patients in a manner that achieves a positive relationship

- Adjusting communication strategies for age, stage of development, patients with special needs, and differing cultures (pp 125–127)
- Interviewing techniques (p 129)
- Verbal defusing strategies (p 134)
- Family presence issues (p 131)
- Dealing with difficult patients (pp 134–135)

EMS System Communication

- Communication needed to
 - Call for resources (p 154)
 - Transfer care of the patient (pp 139–141)
 - Interact within the team structure (p 139)
- EMS communication system (pp 149–155)
- Communication with other health care professionals (pp 139–141)
- Team communication and dynamics (p 139)

Documentation

- Recording patient findings (p 156)
- Principles of medical documentation and report writing (pp 156–170)

KNOWLEDGE OBJECTIVES

1. Describe factors and strategies to consider for therapeutic communication with patients. (p 125)
2. Discuss the techniques of effective nonverbal communication. (pp 127–129)
3. Discuss the techniques of effective verbal communication. (pp 129–134)
4. Understand special considerations in communicating with difficult patients, older adults, children, hard-of-hearing patients, visually impaired patients, non-English-speaking patients, and special needs patients. (pp 134–139)
5. Describe how to effectively communicate transfer of care, including delivery of the oral report on arrival at the hospital. (pp 139–141)
6. Understand the basic principles of the various types of communications equipment used in emergency medical services (EMS). (pp 141–149)
7. Describe EMS communication procedures during the following phases of a typical call: notification or initial receipt of call,

- communication with dispatch en route to call, on scene, during transport, on arrival at hospital (or point of transfer), and return to service. (pp 149–152)
8. List the proper sequence of information to communicate in radio delivery of a patient report. (p 152)
9. Describe the use of radio communications, including the proper methods of initiating and terminating a radio call. (pp 152–156)
10. Describe the use of written communication and documentation. (pp 156–157)
11. Explain the legal implications of the patient care report (PCR). (pp 158–160)
12. Identify the information required in a PCR and how to report errors. (pp 164–165)
13. Understand how to document refusal of care, including the legal implications of the patient's decision. (pp 166–169)
14. Discuss state and/or local special reporting requirements, such as for gunshot wounds, dog bites, and abuse. (pp 167–170)

SKILLS OBJECTIVES

1. Demonstrate the techniques of successful cross-cultural communication. (p 128)
2. Demonstrate delivery of a formal oral report during transfer of care. (p 140)
3. Demonstrate how to provide a verbal radio report to the receiving facility. (p 153)
4. Demonstrate a simulated, concise radio transmission with dispatch. (p 150)
5. Demonstrate completion of a PCR. (p 173)

Introduction

Effective communication is an essential component of prehospital care. **Communication** is the transmission of information to another person—whether it is verbal or nonverbal. A fully functional emergency medical services (EMS) communications system links you with other members of your team as well as with responders from other involved EMS, fire, and law enforcement agencies. Timely, clear communication allows a team to work together efficiently and safely. Excellent communication is also an integral part of organizing, summarizing, and transferring information about the patient's care to the nurses and physicians at a receiving hospital. You must know the capabilities of your team's communication system to make the most of the tools available to you and your teammates.

Verbal communication skills are vital for advanced emergency medical technicians (AEMTs). Your verbal skills will enable you to gather information from the patient and bystanders at an emergency scene. They will also make it possible for you to effectively coordinate with and present instructions to the variety of responders who are often present at the scene. Part of verbal communication is having good listening skills that allow you to fully understand the nature of the scene and the patient's problem.

Documentation is the written or electronically recorded portion of the AEMT's patient care interaction that becomes part of the patient's permanent medical record. Documentation such as a **patient care report (PCR)**, also known as a prehospital care report, provides you with an opportunity to communicate the patient's story to others who may participate in the patient's future medical care. This form should be completed only after the patient's condition has been stabilized; actual patient care is always the priority. Adequate reporting and accurate records ensure the continuity of patient care. Complete patient records also guarantee proper transfer of responsibility, comply with the requirements of health departments and law enforcement agencies, and fulfill your organization's administrative policies.

Radio and telephone communications link you and your team with other members of the EMS, fire, and law enforcement communities. This link helps the entire team to work together more effectively and provides an important layer of safety and protection for each member of the team. You must know what your communications system can and cannot do, and you must be able to use your system efficiently and effectively.

This chapter describes the skills and knowledge you need to be an effective communicator and discusses a variety of effective methods of

verbal and nonverbal communication. The various types of communications systems and equipment are discussed, along with an overview of the EMS communication process, including standard radio operating procedures and protocols. The roles of the Federal Communications Commission (FCC) in EMS are also described. The chapter concludes with a discussion about written communication and documentation.

Therapeutic Communication

Communicating with the dispatcher and fellow health care professionals is certainly important for the AEMT—but so is communicating with the patient. The latter, which is called **therapeutic communication**, involves the art and skill of communicating with people on what may be one of the worst days of their lives. Therapeutic communication uses various communication techniques and strategies, both verbal and nonverbal, to encourage patients to express how they are feeling and to achieve a positive relationship with the patient. A professional demeanor and skilled communication techniques are key components of a successful patient–AEMT interaction. This section discusses the factors and strategies that are necessary for therapeutic communication.

How do we communicate? This simple question can be surprisingly complex, as a number of things must be considered during communication (**TABLE 4-1**).

People communicate in a variety of ways, such as through eye contact, body position, and facial expressions. Factors such as culture and age need

TABLE 4-1 Factors and Strategies to Consider During Communication

Age	Eye contact
Body language	Facial expression
Clothing	Gender
Culture	Posture
Educational background	Voice tempo
Environment	Volume

© Jones & Bartlett Learning.

to be taken into consideration during communication. Patients with special needs may require you to consider alternative forms of communication. For example, if the patient is deaf and you cannot communicate using sign language, you may need to communicate by having the patient write down messages.

If you want people to tell you about their problems, then convince them you want to hear what they have to say. Give patients your full attention; do not treat them like they are a bother. There is nothing worse than talking about someone as if they are not there—or worse, as though the person does not even exist. It is unforgivable to ask someone a question that you will just have to repeat later because you did not pay attention to the answer the first time. Jot down the answer. When it is time to communicate, *communicate*. That means you must listen, not just talk. Listening is part of communicating, too—it is part of the two-way exchange that transmits information.

YOU are the Provider

Part 1

At 1623 hours, your ambulance is dispatched to a reported laceration. Three minutes later, you and your partner are en route to the scene, arriving in about 8 minutes. At the scene, law enforcement officers direct you to the backyard, where you find a 23-year-old woman seated at a picnic table. The patient states her drunken boyfriend threw a broken bottle at her, hitting her on her forearm. You see a minor laceration, with no active bleeding on her right forearm. The patient denies having any other injuries.

1. What are some nonverbal forms of communication you can use to perform an effective interview?
2. As a general rule, how close should you be to the patient while you are interviewing?

Words of Wisdom

The Shannon–Weaver communication model was developed to assist in the development of the mathematical theory of communication for Bell Telephone Labs in the late 1940s¹ (FIGURE 4-1). Shannon and Weaver were trying to figure out the math involved in sending information through telephone lines. After its creation, it quickly became apparent that this model had application in areas other than math. Social scientists picked up this model, and it remains a valuable tool in understanding the variables involved in human communication. In the communication model, the sender must take a thought, encode it into a message, and send the message to the receiver. The receiver then decodes the message and sends feedback to the sender.

FIGURE 4-1 Shannon–Weaver communication model.

© Jones & Bartlett Learning.

Age, Culture, and Personal Experience

The thoughts of people are greatly influenced by their personal experiences. For example, an older adult who often experiences great pain may view pain as more of an inconvenience than a problem. A child who has limited experience with pain would likely react much differently. People are also taught to handle pain differently. Some cultures encourage people to express their emotions about illness and injury; others see this kind of expression as a sign of weakness and prefer to remain unemotional in the face of a health issue. Thus, both social and personal influences will shape a person's thoughts.

Patients may talk, make gestures, or write a note to express how they are feeling. Again, culture and

personal experience will shape how people communicate. Consider the difference between the following examples of communication: “I am so sorry to bother you, but my chest hurts a little” versus “Hey! What took you so long? My chest is killing me! Are you going to help me or what?” Both of these messages talk about pain, but they also contain much more information about the people sending them.

The tone, pace, and volume of a person's language tell us about the mood of the person who is communicating. They may also provide some insight into the perceived importance of the message. For example, the patient who is yelling at you may be angry, scared, or both. Take note of not only the words being spoken, but also of how the words are said.

You need to recognize that these concepts of body language and eye contact are often greatly affected by culture. In some cultures, direct eye contact is viewed as impolite, while in other cultures, it is impolite to look away while speaking. Consider the following differences in nonverbal communication:²

- **Hands on hips.** This stance is considered a sign of hostility in Mexico and Argentina.
- **Touching with the left hand.** Islamic and Hindu cultures avoid touching with the left hand, because traditionally this hand was used for unclean functions. It is considered rude and offensive to offer the left hand in greeting.
- **Eye contact.** Avoid direct eye contact to show respect in most Asian, African, Latin American, and Caribbean cultures. Exceptions to this rule include Somali and Brazilian cultures, in which prolonged eye contact is acceptable; these cultures believe it communicates honesty and interest in the recipient.
- **Slouching.** This practice is considered rude in Japan and in Northern European areas.

Another American usage that may be looked on with disfavor is use of hand gestures. The thumbs-up sign that Americans use to indicate “everything is okay” or “ready to go” is actually the equivalent of an extended middle finger in many Arabic and some Latin countries.

The okay sign—made with thumb and index finger circled, and the other three fingers extended—is a standard American gesture meaning “good to

go.” In Latin countries, Germany, Italy, and Russia, it is a reference to the anus. In France, the gesture means zero and can be used to indicate something is worthless. In other cultures, it represents the evil eye. In Japan, it indicates that money is needed, or that coins are preferred.

The extended middle finger is probably the rudest American gesture. In Japan, the middle digit is used as the index finger and has the same significance as pointing. Please remember this fact when providing care to a Japanese family if they seem to “flip you off” when you ask to be shown where it hurts.

Street Smarts

Many people fall short of giving even basic respect in everyday interactions, let alone in a health care environment. In the United States, emphasis is often placed on getting the job done, and many people seem to be too hurried and busy to seem concerned about how they appear to others. We can offend with the abruptness of our behavior. In other cultures, appearance and manners mean everything, and lack of respect is unforgivable. Such an offense can have greater implications in the health care field, where a patient’s impression of care is partly based on the demeanor of the provider.

People tend to translate the messages they receive using their own worldviews. **Ethnocentrism** occurs when you consider your own cultural values as more important when you are interacting with people of a different culture. If you are North American, for example, then you might suspect that a patient is hiding something, afraid, or untrustworthy if the patient looks away from you while you are talking. These conclusions may be true if the two people communicating are from the same culture—but they may not be valid if the partners in the communication exchange come from different backgrounds. Remember, all aspects of communication—eye contact, social distances, body language, and even touching—have a cultural foundation. In Thailand, for example, the touching of the head is reserved for those who are very intimate. This cultural belief can present a problem for you if the patient’s head is bleeding. Try first explaining what you are about to do and asking for

the patient’s permission if the situation is not life threatening.

Cultural imposition takes ethnocentrism to an extreme. Some health care providers may consciously or subconsciously force their cultural values onto their patient because they believe their values are better. For example, consider a child who is brought to the emergency department (ED) with red marks on his back from a traditional Asian healing practice called coining—rubbing hot coins on the child’s back as a treatment for medical illness. The parents explain to the physician that the coining helped for a short time, but now the child seems to be getting sicker. The physician responds angrily to the parents, accusing them of poor parenting and insisting that their practices are harmful (although they are not). This accusation reflects cultural imposition.

Nonverbal Communication

Facial Expressions, Body Language, and Eye Contact

Eye contact and body language are powerful aspects of communication. Consider how dogs interact. When two dogs meet for the first time, they look at each other. The position of the head, shoulders, tail, and back all help to communicate to the other dog. Before they get any closer, the dogs need to understand their new relationship. Who is dominant? Will you hurt me? These questions must be answered quickly.

People communicate using a similar technique. The body language we consciously or subconsciously choose provides more information than words alone. Consider the images in **FIGURE 4-2**. Without any words, it should be clear what each person’s mood is.

Patients may initially be hostile toward EMS providers, or a calm situation may escalate into a hostile situation. When you are treating a potentially hostile patient, it is important that you understand and be aware of your own body language. People tend to react to anger with anger. If you are dealing with an angry patient, then the last thing you want to do is become angry. Be aware of your body language. Do not assume an aggressive posture. Make good eye contact, but do not stare. Speak calmly, confidently, and slowly. Give the patient choices, but limit those choices to ones you

**A****B****C****FIGURE 4-2** Examples of body language. **A.** Happy. **B.** Angry. **C.** Sad.

can live with. Do not be drawn into the verbal violence your patient may be projecting. Remember, your patient cannot make you angry if you do not allow it to happen.

It is important for you to be attentive to facial expressions, body language, and eye contact—your own and your patient’s. These physical cues will help you and your patient to truly understand the message being sent.

Physical Factors

Various physical factors affect communication, which are collectively referred to as noise. **Noise** is anything that dampens or obscures the true

TABLE 4-2 Proxemics for American Culture

Space	Distance	Description
Intimate	Less than 18 in. (46 cm)	Whispering, touching; must be invited
Personal	18 in. to 4 ft (46 cm to 1 m)	Conversations with close friends or family
Social	4 to 10 ft (1 to 3 m)	Conversations with acquaintances
Public	10 to 25 ft (3 to 8 m)	Interacting with strangers

© Jones & Bartlett Learning.

Safety

Proxemics is typically discussed in a social or cultural context; that is, it helps us understand how physical space affects our interactions and relationships with others. However, in the context of active transmission of aerosolized viral disease, such as COVID-19, physical space has a different significance. It is important to maintain a safe distance (at least 6 feet) when you are not providing care. As important as it is to wear appropriate personal protective equipment, such as gloves, an N95 mask, and eye protection, and to place a surgical mask on any patient showing signs of possible COVID-19, such items should not be considered an absolute safeguard against disease transmission. Likewise, even placing the patient on oxygen via nonrebreathing mask does not prevent exposure to exhaled breath. Social distancing, whenever possible, is vital to ensuring your own safety as well as that of the patient.

meaning of the message. Literal noise, or sounds in the environment, can make it difficult to understand the patient or for the patient to understand you. Lighting, distance, or obstacles are other factors that may affect your communication.

Proxemics is the study of space and how the distance between people affects communication (**TABLE 4-2**). The appropriate distance depends on the levels of trust and intimacy between the two parties. As a person gets closer, a greater and greater sense of trust must be established. When you finally enter someone’s intimate space, there must be a high sense of trust.

Understanding how communication works and the importance of effective communication is important when gathering information from the patient. Your communication skills will be put to the test when you communicate with patients

and/or families in emergency situations. Remember, someone who is sick or injured is scared and might not understand what you are doing or saying. Therefore, your gestures, body movements, and attitude toward the patient are critically important in gaining the trust of both the patient and family.

Street Smarts

Anyone who has dealt with people experiencing a crisis can tell you that a smile can greatly help relieve stress. Think back to a time when you were troubled by something and someone's smile told you that everything was going to be okay. Your ability to smile can be just as valuable when you are communicating with patients, especially to those who are hard of hearing or who speak a different language. Likewise, the tone of your voice can be either harsh or soothing. Pay particular attention to tone of voice when wearing a mask that prevents the patient from seeing your smile.

Verbal Communication

As an AEMT, you must master many communication skills, including those associated with radio operations and written communications. Skilled verbal communication with the patient and family, bystanders, and the rest of the health care team is an essential part of high-quality patient care. It will make it possible for you to effectively coordinate the variety of responders who are often present at the scene, transfer the patient's care to nurses and physicians at the hospital, and listen to fully understand the nature of the scene and the patient's problem. You must also be able to organize your thoughts quickly and accurately to verbalize instructions to the patient, bystanders, and other health care professionals.

One of the most fundamental aspects of what AEMTs do is to ask patients questions (TABLE 4-3). There are two types of questions: **open-ended questions**, which require the patient to provide an answer with some level of detail, and **closed-ended questions**, which can be answered in short or single-word responses. When you first approach your patient, you should use open-ended questions: "Good day. My name is Chuck and I am an AEMT. What seems to be bothering you today?" Open-ended questions allow a free flow of

TABLE 4-3 Types of Patient Interview Questions	
Open-ended questions	Questions without a definitive, "yes" or "no" answer. Let patients describe their pain in their own words because those will probably be more accurate. The following are some examples of open-ended questions: • How have you been feeling lately? • Do you have an idea of what is causing this? • Do you have any other concerns about your health? • Is there anything else you would like to discuss?
Closed-ended questions	Questions with a definitive answer. Develop a standard set of questions concerning medical history that you ask almost all patients, using words that people without medical training can understand. Your standard questions may include the following: • Have you ever had any heart problems? • Any lung problems? • Any high or low blood pressure? • Diabetes? • Seizures? • Fainting spells? • Any prior head injury? • Do you have both lungs and both kidneys?

© Jones & Bartlett Learning.

conversation. They let the patient direct you to what is bothering them.

Closed-ended questions are important to use when patients are unable to provide long or complete answers to questions. Perhaps the patient is having severe breathing difficulties, or maybe the patient is a child who is scared and does not know what to say. In situations for which thoughtful answers are not possible, closed-ended questions are appropriate and are particularly useful when assessing a patient's condition. "Are you having trouble breathing? Do you take medications for your heart?"

However, with closed-ended questions it is possible for you to miss important information if pertinent questions are not asked. Imagine how many ways a person can be sick or injured. Now imagine trying to come up with a single yes/no question for each sickness or injury. Closed-ended questions

typically provide limited information, and you should consider the answers to these questions as only a starting point toward understanding the patient's condition.

Other types of questions that can reveal underlying issues include the following payoff questions. These were developed by AEMTs based on field experience:

- Have you ever felt like this before?
- Have you been upset about anything lately?
- Are you afraid of someone? (Save this one for the privacy of the ambulance.)
- Have you been thinking about hurting yourself?
- What happened the last time you felt this way?

When you are asking questions of the patient, be alert to how many questions you are asking: "How are you doing today? Have you been feeling ill?" This common approach asks the patient two kinds of questions, one open-ended and one closed-ended. Often the patient will respond with a simple "yes." To avoid this situation, it is best to ask a single question, wait for an answer, and then ask another question.

Many powerful communication tools can be used when trying to obtain information from patients. Sometimes patients will hide information, either consciously or unconsciously. Patients may be afraid or they may be confused. Children are easily distracted, so a toy may be used to focus their attention and facilitate communication. The techniques in **TABLE 4-4** are tools that can assist you in

TABLE 4-4 Communication Tools

Communication Tool	Meaning	Example
Facilitation	Encourage the patient to talk more or provide more information.	AEMT: "Can you tell me more about that? I am listening to you."
Silence	Do not speak.	Giving the patient space and time to think and respond.
Reflection	Restate a patient's statement made to you to confirm your understanding.	Patient: "I am so depressed that I could die." AEMT: "I understand that you are feeling sad."
Empathy	Be sensitive to the patient's feelings and thoughts.	Use eye contact and touch to reinforce your communication; adjust your tone of voice and pace to allow for open communication.
Clarification	Ask the patient to explain what was meant by an answer.	Patient: "I just feel sick." AEMT: "Please tell me what you mean by 'feeling sick'? Help me to understand what is going on."
Confrontation	Make the patient who is in denial or in a mental state of shock focus on urgent and life-critical issues.	Patient: "I am having pain in my chest, my back has been hurting me, I feel nauseated, and I ran out of my blood pressure medication." AEMT: "Please tell me about your chest pain. We will talk about your other concerns in a moment."
Interpretation	Sum up the patient's complaint to confirm your understanding.	AEMT: "If I understand correctly, you have been feeling pain for the past 3 days, and it has gotten worse today." Patient: "That's right."
Explanation	Provide factual information to support a conversation.	Patient: "I do not understand what is happening." AEMT: "We have checked your blood sugar and blood pressure and both appear to be normal."
Summary	Provide the patient with an overview of the conversation and the steps you will take.	AEMT: "We will be taking you to the emergency department to care for your chest pain. I will give you some medication that should make you feel better."

gathering patient information. They can be helpful to use not only in patients who are willing to share, but also in those who are resistant to sharing information.

When you are interviewing the patient, you can consider using touch as a means to communicate caring and compassion. Touch is a powerful tool, so it should be used both consciously and sparingly (**FIGURE 4-3**). Many people will be uncomfortable with a stranger suddenly touching them. If you are going to touch the patient, then approach slowly and touch the patient's shoulder or arm respectfully. You may hold the patient's hand. This allows you to touch the patient, showing you care about what the patient is telling you, yet also allows you to remain at a slight distance.

Avoid touching the patient's torso, chest, or face simply as a means of communication, because these areas are often viewed as intimate. Also, to touch these areas, you will need to get closer to the patient, potentially invading the patient's intimate space. **TABLE 4-5** provides other tips on what to avoid when communicating with patients.

The presence of family, friends, and bystanders during your interview of the patient can be valuable. Sometimes, however, well-meaning family members will speak for the patient, and, at times, you may need to ask the family member to allow the patient to answer. Ultimately, you will need to assess the situation and determine whether the additional people are helping you care for the patient or hindering your efforts. Do not be afraid to ask others to

step outside or step aside for a moment while you talk with the patient. Consider how the patient will feel not having loved ones nearby. Removing them may make the patient more anxious.

These 10 Golden Rules will help you to calm and reassure the patient and provide a therapeutic rapport:

1. **Establish rapport.** Establishing a rapport means building a trusting relationship with your patient. This will make caring for the patient much easier. Use the following techniques to develop rapport:
 - Maintain eye contact with the patient at all times. Give the patient your undivided attention. This will let the patient know that they are your top priority. Look the patient straight in the eye to establish a rapport.
 - Watch your inflection. Use a calm and steady tone of reassurance to reinforce your interest in and concern for the patient.
 - Respond to the patient. Acknowledge what the patient is telling you. If you are not comfortable responding, then simply nod or restate what the patient said, without providing a definitive answer right away.
 - Anticipate and deal with fear. Reassurance may be one of the most important treatments you can provide.
 - Respect the importance of pain. People deserve to have their pain relieved to the extent that it is safe and feasible—with a medical consultation if necessary.
 - Respect and protect people's modesty. This is especially important when treating the very old, adolescents, and, sometimes, the very young **FIGURE 4-4**.
2. **Provide your name and use the patient's proper name.** Introduce yourself and your partner. If your department provides you with a name tag, then wear it. Ask the patient what they wish to be called. Avoid using terms such as "honey" or "dear." Use only a patient's first name if the patient is a child or the patient asks you to use a first name. Otherwise, use a courtesy title, such as "Mr. Peters," "Mrs. Smith," or "Ms. Butler." If you do not know the patient's name, then refer to the person as "sir" or "ma'am."
3. **Tell the patient the truth.** Even if you have to say something very unpleasant, telling the

TABLE 4-5 Interview Techniques to Avoid

Improper Technique	Example	Reason
Providing false assurance or reassurance	AEMT: "It will be okay." "This is nothing to worry about."	You really do not know that everything will be okay.
Giving unsolicited advice	AEMT: "Well, if I were you, I wouldn't have called the ambulance at all."	This demeans the patient and makes you seem arrogant rather than helpful. It is inappropriate to suggest that an ambulance was not needed, even if that is what you believe.
Asking leading or biased questions	AEMT: "Are you telling me that this cut is the only reason you called the ambulance?"	Your patient deserves respectful communication. It is inappropriate to suggest that an ambulance was not needed, even if that is what you believe.
Talking too much	The AEMT talks to the patient without really listening to the patient, simply going through the motions.	Guide the patient through the conversation. When the patient provides you information, you need to consider the information and move the conversation toward a goal.
Interrupting the patient	Patient: "Well, I was having trouble breathing the past month and . . ." AEMT: "Can we move on to how you are feeling now?"	You may seem bored or annoyed that the patient is taking up your time.
Using "why" questions	AEMT: "Why did you call the ambulance today?"	"Why" questions often appear to accuse the listener. You may seem annoyed that the patient called 9-1-1.
Using authoritative language	AEMT: "Tell me what is wrong with you." "Just give me the details."	This language does not encourage open communication.
Speaking in professional jargon	AEMT: "I think we will need to take you to the ED stat. We will give you ASA and NTG en route. Any questions?"	This type of communication confuses the patient. Most patients do not understand medical jargon. It is also abrupt and may deter open communication.

truth is better than lying. Lying will destroy the patient's trust in you and decrease your own confidence. You might not always tell the patient everything, but if the patient or a family member asks a specific question, you should answer truthfully. A direct question deserves a direct answer. If you do not know the answer to a patient's question, then say so. For example, a patient may ask, "Am I having a heart attack?" You might then answer, "I don't know, but we will certainly get more information at the hospital. Right now, I am providing you with all the care needed for a person who may be having a heart attack."

4. **Use language that the patient can understand.** Do not talk up or down to the patient

in any way. Avoid technical medical terms that the patient might not understand. For example, ask the patient whether they have a history of “heart problems.” This will usually result in more accurate information than if you ask about “previous episodes of myocardial infarction” or a “history of cardiomyopathy.”

5. **Be careful what you say about the patient to others.** You need to understand the relationship between the person you are talking with and the patient. Does the patient want you talking with this person? Ask the patient if it is okay to talk with this person. While speaking to others, ensure you leave the general area of the patient if you must have a confidential conversation. Be mindful that sharing patient information may be a violation of the Health Insurance Portability and Accountability Act (HIPAA).
6. **Be aware of your body language.** Nonverbal communication is extremely important in dealing with patients. In stressful situations, patients may misinterpret your gestures and movements. Be particularly careful not to appear frustrated or threatening. Instead, position yourself at the same level or at a lower level than the patient when practical. Remember, always conduct yourself in a calm, professional manner.
7. **Always speak slowly, clearly, and distinctly.** Pay close attention to your tone of voice.
8. **If the patient is hard of hearing, face the person so they can read your lips.** Do not shout at a person who is hard of hearing; shouting will not make it any easier for the patient to hear you. Shouting may also frighten the patient and can end up making communication with the patient even more difficult. Never assume an older adult patient is hard of hearing or otherwise unable to understand you. Also, never use “baby talk” with older adult patients or with anyone other than infants.
9. **Allow time for the patient to answer or respond to your questions.** Do not rush a patient unless there is immediate danger. Sick and injured people may not be thinking clearly and may need time to answer even simple questions. This is especially true when treating older adult patients.
10. **Act and speak in a calm, confident manner while caring for the patient.** Ensure you

attend to the patient’s pains and needs. Try to make the patient physically comfortable and relaxed. Find out whether the patient is more comfortable sitting or lying down. Is the patient cold or hot? Does the patient want a friend or relative nearby?

Patients place their lives in your hands. They deserve to know that you can provide medical care and that you are concerned about their well-being. These 10 Golden Rules will help provide a good foundation and will make it easier to gather information when the patient wants to talk.

Emotional Intelligence

Emotional intelligence is the ability to understand and manage your own emotions and properly respond to others’ emotions. Sometimes referred to as people skills, emotional intelligence can help AEMTs defuse conflict, build a rapport, communicate more effectively, and manage difficult situations. Emotional intelligence is commonly understood to have five attributes.

1. **Self-awareness.** The ability to recognize your own emotions and how they affect your thoughts and behavior.
2. **Self-regulation.** The ability to control impulsive emotions and behaviors and to manage emotions in positive ways.
3. **Motivation.** The ability to motivate yourself and others in a positive direction, often deferring short-term rewards for long-term success.
4. **Empathy.** The ability to understand the concerns, emotions, and needs of others by picking up on communication and social cues and clues.
5. **Social skills.** The ability to develop and maintain positive rapport and relationships through effective communications.

Think of people in your life whom you consider kind, caring, and really good listeners. These are people with high emotional intelligence. They can identify, understand, and manage their own emotions and the emotions of others.

As an AEMT, you should seek to understand and improve your own emotional intelligence. Consider the following tips:

- Assess how you react to stressful situations. Do you become upset by every little frustration,

such as delays, people not performing tasks correctly, or things not going your way? Try to manage your frustration, and work on staying calm and in control when faced with minor irritations.

- Practice mindfulness. Purposely focus your attention on the present moment, without blame and judgment of yourself or others. Doing so can help calm and focus you and make you more aware of the situation around you.
- Take responsibility for your actions. Do not be quick to blame or attack others if things do not go your way. Acknowledge your own role in the situation.
- Consider how your actions will affect others before you take those actions. Think about how your words and actions will make others feel.

When communicating in difficult situations, especially when high levels of emotion are involved, a communication method known as the behavioral change stairway model may be helpful. This five-step model was developed by the Federal Bureau of Investigation to manage hostage negotiations quickly and effectively. It can be adapted to most crisis communications. Each step should be followed in order, as each step builds on the previous step(s) to help improve communications, build rapport, and deescalate crisis situations.³

1. **Employ active listening.** Carefully listen to what the other person has to say and let the person know you are doing so. Acknowledge what the person is saying, and do not interrupt, disagree, or give commands.
2. **Display empathy.** Use your emotional intelligence to understand the patient's perspective. You do not have to agree with the person or condone the person's actions, but you have to understand where the person is coming from and what the person wants.
3. **Build a rapport.** Once you have listened to the person and understand where the person is coming from, it is much easier, especially in a crisis, to empathize with the person and "speak the person's language."
4. **Exert influence.** Look at realistic solutions to move the situation forward in a positive way. Understanding the other person's perspective along with your own needs, consider how you can move forward in a way the person will

understand. Initiate behavior change: propose a solution that makes sense to the other person and is acceptable to you.

5. **Initiate behavioral change.** From an EMS perspective, our goal in this step is to create a nonthreatening environment for all involved. All parties involved must reach an acceptable solution that is a culmination of the previous steps.

Communicating With Specific Types of Patients

Difficult Patients

Sometimes, you need to gather information from a reluctant patient. For example, some patients may be defensive about their problems and may not want to talk about them because they are embarrassed. They may direct the conversation away from the true problem. With these patients, start the conversation as usual. Introduce yourself. Be open and compassionate. If you find yourself not getting any real answers, then consider using one of the techniques discussed later in this section.

On some occasions, patients may become hostile toward EMS providers. To help defuse these potentially escalating circumstances, stay calm. Talk to the patient openly and honestly. You will find that meeting hostility with calmness and confidence defuses a situation. Use open-ended questions, provide positive feedback, ensure the patient understands the questions, and continue to calmly ask questions. At the same time, consider the safety of the scene. Decide whether you need law enforcement. Ensure you have sufficient backup to provide safety for the patient and the crew. Then, with your backup clearly visible, calmly advise the patient what needs to be done: "Sir, I need you to sit on the ambulance stretcher now. You may proceed to the stretcher or we can help you to the stretcher." No one should threaten the patient, and no one should move toward the patient. In this rare circumstance, you are providing the patient with choices, while at the same time limiting those choices to ones you can accept.

You are guaranteed to receive some unpleasant insults from people who are in crisis, especially from patients who are chemically impaired or under the influence of street drugs or alcohol. Discipline yourself never to respond in kind. Nothing escalates

a situation faster than trading insults. Frequently, there are plenty of witnesses and you could experience legal ramifications from your disrespectful behavior. Nevertheless, you should consider the possibility that you may not be able to defuse someone's anger. If the situation gets out of control, then you may have to defer to law enforcement.

Your primary responsibility is to yourself and your partner—that is, to ensure scene safety. It is imperative to recognize the potential for violence and to react accordingly. Call for law enforcement as soon as you have reason to believe you may be encountering a difficult patient. This assistance may be sought en route to the call based on information obtained by the dispatcher. Remember, it is better to have law enforcement and not need them than to wait until the situation escalates before calling for help.

You may also encounter patients who are sexually aggressive. In this instance, simply changing caregivers may solve the problem. If not, then firmly explain to the patient that this is not an option and that the individual will be turned over to law enforcement if the behavior continues. In most situations, simply rebuking the advancement is enough to stop the aggression. However, if drugs or alcohol are involved, bringing in law enforcement for restraint may be necessary.

Older Adult Patients

You should not assume communicating with older adults will be more difficult than communicating with anyone else just because of their age. However, older adults' illnesses tend to be more complex than the illnesses of younger people, because they may have more than one disease or disorder and they may be taking multiple medicines concurrently. You may note individual differences among members of the geriatric population related to hearing, eyesight, mental status, and mobility; you need to adapt to them. **TABLE 4-6** lists techniques to employ when interviewing an older adult; note that these same techniques actually apply to most any patient.

In general, older adults think clearly, can give you a clear medical history, and are able to answer your questions appropriately. Do not assume an older adult is senile or confused. Also, do not assume that hostility, irritability, and confusion are normal behavior for older adults: these signs may

TABLE 4-6 Interviewing Older Adult Patients

Identify yourself. Do not assume the older adult patient knows who you are.
Be aware of how you present yourself. Frustration and impatience can be portrayed through body language.
Look directly at the patient.
Speak slowly and distinctly.
Explain what you are going to do before you do it. Use simple terms to explain the use of medical equipment and procedures. Avoid medical jargon or slang.
Listen to the answer the patient gives you.
Show the patient respect. Refer to the patient as Mr., Mrs., or Ms.
Never assume that an altered mental status is normal. Establish a baseline mental status and, if different from usual, quickly assess for hypoxia and hypoglycemia.
Do not discuss patients in front of them; doing so gives the impression that the patients have no choice in their medical care. This point is easy to forget when the patient has impaired cognitive (thought) processes or has difficulty communicating.
Be patient!

© Jones & Bartlett Learning.

be caused by a simple lack of oxygen (hypoxia), brain injury including a cerebrovascular accident, unintentional drug overdose, or even hypovolemia. Never attribute altered mental status to old age. Some older adult patients may have difficulty hearing or seeing you, so exercise great patience and compassion when you are called on to care for these patients. Think of the patient as someone's grandmother or grandfather, or even as yourself when you reach that age. Approach an older adult slowly and calmly. Allow plenty of time for the patient to respond to your questions.

Older adult patients often do not feel much pain. In fact, an older adult who has fallen or been injured may report no pain. Likewise, older adult patients might not be fully aware of important changes in their body systems. Therefore, be especially vigilant for objective changes—no matter how subtle—in their conditions. Objective changes are those that any observer would be able to witness. For example,

respiratory rate, heart rate, sweating, or vomiting are all objective findings. Subjective findings are those that only the patient can experience, such as pain or nausea. Even minor changes in breathing or mental state may signal major problems.

Special Populations

When possible, give the patient time to pack a few personal items before leaving for the hospital. Document on the PCR that these items accompanied the patient and the person to whom they were given in the ED.

Children

Children can be challenging patients because they pose communication challenges and will likely be very frightened. They tend to protest pain vigorously, they may be afraid of strangers (including you), they may panic when separated from their parents, and their bodies may not be as familiar to many of us as are the bodies of adults. However, with a little practice, you can become comfortable treating children.

Equipment (such as stethoscopes or needles) is not as important early in your contact with children as are friendly eye contact, smiles, and calm, subdued explanations, geared to match each child's age. Discipline yourself to minimize your movements, lower your voice, and touch as gently as you can. Try placing yourself at or below the child's eye level, for instance, by sitting on the floor and placing the child on the cot or on a parent's lap (**FIGURE 4-5**). If possible, then involve a parent in the hands-on care of an alert small child (for instance, by holding an extremity while you insert an intravenous [IV] line). This is much less effective when treating older children, but is more important with infants and toddlers. If you are caring for a noncritical pediatric patient, then demonstrating the assessment procedure (eg, taking blood pressure) on a sibling or parent can often put the child at ease and facilitate assessment.

Toys are useful for bridging the emotional gap between AEMTs and some children. Many crews stock their ambulances with stuffed animals for toddlers. If those kinds of toys are not available, then you can make a serviceable chicken out of an

FIGURE 4-5 When you are examining a very young child, involve the parents. Consider having the father hold the child on his lap, or asking the mother to keep the child occupied while you examine the child.

Photo Illustration by Craig Jackson in the dark photography.com.

exam glove by inflating the glove and marking its eyes with a felt marker; however, these can pose a choking hazard and cannot be left with the child at the end of the encounter. You are more likely to connect with the child if you do this right in front of the child rather than if you ask someone else to do it.

Children can easily see through lies or deceptions, so you must always be honest with them. Explain to the child repeatedly what is happening. If treatment will hurt, such as applying a splint, then tell the child ahead of time.

Respect a child's modesty. Children are often embarrassed if they have to undress or be undressed in front of strangers. This anxiety often intensifies during adolescence. When a wound or site of injury has to be exposed, try to do so out of the sight of strangers, and when appropriate ensure a parent or guardian is present. Again, it is extremely important to tell the child what you are doing and why you are doing it.

Hard-of-Hearing Patients

Patients who are hard of hearing or deaf are usually not ashamed or embarrassed by their disability. Often, it is the people around a deaf or hard-of-hearing

Special Populations

When you are assessing children, it is important to give choices so that they feel involved in their care. However, do not give yes or no choices:

- Do not ask: “Can I touch you?”
- Instead ask: “I need to listen to your heart and touch your tummy. Which would you like me to do first?”

While still involving the child in the decision process, you are not limiting your assessment.

person who have difficulty coping. Remember, you must be able to communicate with hard-of-hearing patients so you can provide necessary or even life-saving care.

Hard-of-hearing patients have normal intelligence. They can usually understand what is going on around them, provided that you can successfully communicate with them. Most patients who are hard of hearing can read lips to some extent. Therefore, it may be valuable to remove your mask and place yourself in a position so that the patient can see your lips. Remember to maintain social distancing, especially when not wearing a mask. Wearing a mask with a clear window, when available, will also allow patients to read your lips.

Many hard-of-hearing patients have hearing aids to help them communicate. Be careful that hearing aids are not lost during an accident or fall. Hearing aids may also be forgotten if the patient is confused or ill. Look around, or ask the patient or the family about a hearing aid.

Remember the following five steps to help you efficiently communicate with patients who are hard of hearing:

1. **Have paper and a pen available.** This way, you can write down questions and the patient can write down answers, if necessary. Be sure to print clearly so your handwriting is not a communication barrier.
2. **If the patient can read lips, then face the patient and speak slowly and distinctly.** When masks are required because of an ongoing risk in the community of disease transmission, consider removing your mask for brief periods to communicate necessary information only outdoors and only if you are able to remain more than 6 feet from the patient.
3. **Never shout.** This will not help the patient hear you and may frighten them.
4. **Listen carefully, ask short questions, and give short answers.** Remember, although many hard-of-hearing patients can speak distinctly, some cannot.
5. **Learn some simple phrases in sign language.** For example, knowing the signs for “sick,” “hurt,” and “help” may be useful if you cannot communicate in any other way (**FIGURE 4-6**).

Visually Impaired Patients

Like patients who are hard of hearing, visually impaired and blind patients have usually accepted and learned to deal with their disabilities. Of course, not all visually impaired patients are completely blind. Many can perceive light and dark

FIGURE 4-6 Learn simple phrases in sign language. **A.** Sick. **B.** Hurt. **C.** Help.

Safety

Removing your mask may not be an option when the risk of exposure to a disease, such as COVID-19, is high and social distancing is not possible. It is impossible to maintain a space of 6 feet in the back of an ambulance, so improvisation may be required to communicate with the patient.

or can see shadows or movement. Ask the patient whether they have any vision. Also, remember, as with other patients who have disabilities, you should expect visually impaired patients to have normal intelligence.

As you begin caring for a visually impaired patient, explain everything that you are doing in detail as you are doing it. Stay in physical contact with the patient as you begin your care. Hold your hand lightly on the patient's shoulder or arm. Try to avoid sudden movements. For patients who can walk to the ambulance, place their hand on your arm, taking care not to rush. Transport any mobility aids, such as a cane, with the patient to the hospital.

Some visually impaired people may have a guide dog. Guide dogs are easily identified by their special harnesses. They are trained to not leave their owners and to not respond to strangers. A visually impaired patient who is alert can tell you about the dog and give instructions for its care. If circumstances permit, then bring the guide dog to the hospital with the patient. If the dog has to be left behind, then you should arrange for its care.

Non-English-Speaking Patients

Part of patient care includes obtaining a medical history from the patient. You cannot skip this step simply because the patient does not speak English. Most patients who do not speak English fluently will still know certain important words or phrases.

Your first step is to find out how much English the patient can speak. Use short, simple questions and simple words whenever possible and avoid difficult medical terms. You can help patients better understand if you point to specific parts of the body as you ask questions. Speaking louder will not increase a patient's ability to understand you.

In many areas, particularly large urban centers, major segments of the population do not speak

English. Your job will be much easier if you learn some common words and phrases in their language, especially common medical terms. Pocket cards that show the pronunciation of these terms are available. If the patient does not speak sufficient English to effectively communicate, then use a smartphone app or website to help you translate, or find an interpreter. You should understand where to find these online resources in advance and have access to them ready at all times, particularly if you are working in an area where language barriers are prevalent. In an emergency, it may be necessary to have a family member or friend translate until a professional interpreter is located. Also, remember to request a translator at the hospital while providing the radio report if the patient's language is known.

Street Smarts

Familiarize yourself with the languages spoken in your area of practice and learn how to interact with members of each culture accordingly. You may not get everything right when you encounter a representative from one of these groups, but your efforts at communicating will translate the idea of respect, and that makes all the difference.

When communicating with the help of an interpreter, look at the patient as you ask questions and listen to the interpreter's answers. Keeping your eyes on the patient allows you and the patient to interpret body language that accompanies verbal communication and maintains the relationship with the patient. Direct your questions to the patient and avoid the use of medical terminology when possible to minimize the risk of misunderstanding.

Special Needs Patients

It would be a mistake to overlook the needs of people who have speech or other kinds of communication disorders. When you encounter a patient who has trouble communicating, remember that family members or primary caregivers who know these patients well can facilitate your efforts. Just as importantly, they can also help you to alleviate fear.

Many caregivers find that touch and eye contact are helpful bridging mechanisms when dealing with some of these patients. For example, a light touch on a patient's shoulder can convey kindness, while a firm grasp can express reassurance. Some patients respond well to brief, one-armed hugging.

Another group of patients that providers are beginning to encounter more often are those with autism.⁴ People with autism may have difficulty developing language skills and understanding what others say to them. They may also have difficulty communicating nonverbally, such as through hand gestures, eye contact, and facial expressions. However, not every person with an autism spectrum disorder will have a language problem. A person's ability to communicate will vary depending on the person's intellectual and social development. If you encounter difficulty when communicating with a patient with autism, then it may be best to address questions to the caregiver. Most caregivers have developed knowledge of the patient's needs through years of working with the patient. They are your best resource for communicating with the patient with an autism spectrum disorder.

Transfer of Patient Care

Effective communication with other health care professionals in the receiving facility is a cornerstone of efficient, effective, and appropriate patient care. Your reporting responsibilities do not end when you arrive at the hospital—in fact, they have just begun. Patient care is a coordinated effort among numerous providers, from bystanders and first responders to paramedics, from primary care physicians to ED nurses, and beyond. Nowhere is communication more important than during the transfer of patient care.

General Guidelines

If possible, a single person—the team leader—should coordinate the patient's transfer of care and report the patient information. Whenever the verbal transfer of care occurs, all team members should do their best to ensure the following:

1. **Uninterrupted critical care.** Whenever possible, the team member giving the report and the team member taking the report should hand off life-saving care (such as performing chest compressions) to another team member, allowing them to focus on the transfer of care.
2. **Minimal interference.** The transfer of patient care should occur in a location with the least interference possible. If the transfer takes place at the patient's side, it should not occur while the patient is being moved.
3. **Respectful interaction.** Each team member involved in the transfer must be respectful of members' different roles and recognize the importance of each role.
4. **Common priorities.** Both the team member giving the report and the team member taking the report must focus on their common priorities (critical assessment findings and patient care) vital for the best possible patient outcome.
5. **Common language or system.** Whenever possible, a mutually agreed-on and standardized patient handoff format should be used.

Giving the Handoff Report

Although effective health care teams work together from first patient contact to patient discharge, not all providers will be present throughout the entire continuum of care. At several points along the continuum, the patient's care will be transferred, or “handed off,” from one unit of providers on the team to another. These transfers introduce the possibility of critical patient care errors, especially when they occur several times and in different settings along the continuum of care. Effective teams minimize the number of transfers during patient care and adhere to strict and careful guidelines when such transfers are unavoidable.

Just like in a relay race, a proper transfer of patient care will allow the team to keep moving forward with patient care. When incorrect information is handed off, information is miscommunicated, or care is interrupted, the team is forced to move backward, resulting in a loss of valuable time and effort. For this reason, it is important for you to trust other team members—even those who work at different levels or for various agencies. For example, if an emergency medical responder (EMR) reports a patient had a syncopal episode, but the patient is now alert, do not assume the EMR's information is incorrect.

Even on a single emergency call, an AEMT may be involved in numerous patient care handoffs. For example, a first responder or primary-care medical provider may hand off patient care on arrival of an AEMT, the AEMT may hand over care on arrival of a paramedic, and the AEMT-paramedic team may hand over care to the ED staff (**FIGURE 4-7**). As common as this occurrence may be, it is a hazardous one. The American College of Emergency

© Jones & Bartlett Learning.

Physicians has called patient handoff “the most dangerous point in a patient’s ED journey,”⁵ and the World Health Organization has identified communication during patient handoff as a critical failure point that can cause “serious breakdowns in the continuity of care, inappropriate treatment, and potential harm to the patient.”⁶ Furthermore, communication failures between reporting providers and receiving providers is a major source of medical liability for providers and organizations, accounting for 30% of malpractice claims in all health care sectors, including EMS.

The care provider giving the report should observe the following:

- **Initiate eye contact.** When handing over patient care, responsibility, and information, it is critical to begin by making eye contact with the person to whom the patient is being transferred.
- **Manage the environment.** Whenever possible, try to minimize noise, interruptions, and distractions by, for example, momentarily turning down a radio, stopping nonpriority activities, or moving to a quieter area to give the report. Avoid moving the patient during the handoff report so all attention is focused on the patient information.
- **Ensure the ABCs.** If there is priority critical care that must be initiated or continued, it must be immediately conveyed and addressed by the receiving clinician or team. Such care

includes life-saving interventions that are either needed immediately (eg, the application of a tourniquet) or that must be continued (eg, cardiopulmonary resuscitation [CPR]) for the patient to survive.

- **Provide a structured report.** Research on mission-critical communications has shown that the use of a structured format greatly improves efficiency and reduces errors. Numerous standardized report formats exist. One format, SBAR (which stands for situation, background, assessment, and recap/Rx) is widely used in hospitals and is likely to be well understood by a variety of health care providers. The mnemonic is sometimes modified slightly to SBAT when used in EMS:
 - Situation (a concise statement of the problem)
 - Background (relevant, brief information about the patient situation)
 - Assessment (your assessment findings and what you think)
 - Treatment (care that has been provided to the patient)
- **Supply documentation.** The verbal report should consist of the patient’s priority conditions, any pertinent allergies and comorbidities, prior care, current state, and immediate needs. The numerous other patient details should be transferred via a paper or electronic report. Avoid clouding the handover with information that is not immediately critical.

As an AEMT, you will also need to communicate routinely with many other professionals—law enforcement, social service personnel, fire personnel, and other EMS providers. Ensure your language and general demeanor are professional. Remember,

Words of Wisdom

In 1996, HIPAA established mandatory patient privacy rules and regulations to safeguard patient confidentiality.⁷ The act provides guidance on the types of information that are protected, the responsibility of health care providers regarding that protection, and penalties for breaching that protection. For further discussion of HIPAA, see Chapter 3, *Medical, Legal, and Ethical Issues*.

federal laws protect a patient's right to privacy and that you should not give any health information about your patient to anyone other than those directly involved in the care of the patient.

Communications Systems and Equipment

Communication during an emergency call will require the use of specialized equipment. Although the digital revolution is improving communications, most EMS communications systems today are based on the use of radios, so it is important for you to learn about radio signals and to know which equipment is available for sending and receiving those messages.

A key aspect of EMS communications is a reliable method of sending and receiving information back and forth to medical direction. Although this communication has mainly been accomplished by radio in the past, cellular devices and mobile data terminals (MDTs) are becoming more popular ways to share this kind of information. The EMS system must be configured to allow 24-hour methods of contact with medical direction at local and regional facilities.

Although these communications systems are relatively dependable, a backup communications system is also needed. For example, if the primary method of communication is digital radio,

a secondary means might include the use of cell phones, a satellite phone, or an MDT. Having backup communications systems in place ensures there will always be a method to access medical direction, in any circumstance, 24 hours per day.

Backup communications are even more critical in times of disaster or mass-casualty incidents (MCIs). In these situations, primary methods of communications may be disabled. Cell towers may be damaged, cell sites may be disabled, and computer data servers may be crippled. In these circumstances, disaster communications are often established by amateur radio groups. Most of the equipment for this type of communication is available after a major incident through your local emergency management office.

No matter which type of system you are using for EMS communications, you must know what that system can and cannot do, and you must be able to use your system efficiently and effectively. You must be able to send precise, accurate reports about the scene, the patient's condition, and the treatment that you provide. Thus, you must know when to use your communications equipment and what to say when you are transmitting (effective radio communications is discussed later in this chapter).

At the same time, you must recognize that the information shared through EMS communications systems is subject to some constraints. Under HIPAA

YOU are the Provider

Part 2

While you are interviewing the patient, bystanders come out of the house and start raising their voices, stating, "He didn't throw anything at you. You did that to yourself!" Recognizing that her friends are intoxicated and that this scene could easily escalate, you request that law enforcement officers remove the disruptive parties.

3. What are two types of questions that are asked during a patient interview?
4. Which techniques can be used to deescalate difficult situations?

regulations, most personal health information is considered protected and should not be released without the patient's permission. These regulations apply to all forms of communication—written and verbal. To ensure that you are protecting your patient's right to confidentiality, do not give any information to anyone other than those directly involved in the care of the patient. When sharing information verbally (eg, by radio or cell phone), ensure unauthorized people nearby cannot overhear the content of that communication. Finally, become familiar with all policies and procedures governing communication established by your agency.

A **scanner** is a radio receiver that searches, or “scans,” across several frequencies and stops when radio traffic is heard until the message is completed. These devices may be used by their owners to eavesdrop on nearby radio traffic. Although cell/satellite telephones are more private than most other forms of radio communications (because they use digital communication, rather than radio frequencies), they can still be overheard. Given that the risk of someone overhearing your messages is essentially omnipresent, you must always be careful to appropriately respect patient privacy and to speak in a professional manner every time you use any form of an EMS communications system.

Regulation of Radio and Telephone Communications

All radio operations in the United States, including those used in EMS systems, are regulated by the **Federal Communications Commission (FCC)**.⁸ The FCC has jurisdiction over interstate and international telephone and telegraph services and satellite communications—all of which may involve EMS activity.

The FCC has five principal EMS-related responsibilities:

1. **Allocating specific radio frequencies for use by EMS providers.** Modern EMS communications began in 1974. At that time, the FCC assigned 10 MED channels in the 460- to 470-MHz (UHF) band to be used by EMS providers. These UHF channels were added to the several VHF frequencies that were already available for EMS systems. However, these VHF frequencies had to be shared with other “special emergencies” uses, including school

buses and veterinarians. In 1993, the FCC created an EMS-only block of frequencies in the 220-MHz portion of the radio spectrum.

2. **Licensing base stations and assigning appropriate radio call signs for those stations.** An FCC license is usually issued for 5 years, after which time it must be renewed. Each FCC license is granted only for a specific operating group. Often, the longitude and latitude (locations) of the antenna and the address of the base station determine the call signs.
3. **Establishing licensing standards and operating specifications for radio equipment used by EMS providers.** Before it can be licensed, each piece of radio equipment must be submitted to the FCC by its manufacturer for type acceptance, based on established operating specifications and regulations.
4. **Establishing limitations for transmitter power output.** The FCC regulates broadcasting power to reduce radio interference between neighboring communications systems.
5. **Monitoring radio operations.** This includes making spot field checks to help ensure compliance with FCC rules and regulations.

The FCC's rules and regulations fill many volumes and are written in technical and legal language. Only a small section (part 90, subpart B) deals with EMS communications issues. You are not responsible for reading these detailed and often complex documents. For appropriate guidance on technical issues, contact your EMS systems' supervisor. In fact, many EMS systems look to radio and telephone communications experts for advice on technical issues.

Radio Communications

As an AEMT, you must be familiar with two-way radio communications and have a working knowledge of the mobile and handheld portable radios that are used in your unit. A two-way radio consists of two units: a transmitter and a receiver. Some base stations may have more than one transmitter and/or more than one receiver. They may also be equipped with one multichannel transmitter and several single-channel receivers. A **channel** is an assigned frequency or frequencies used to carry voice and/or data communications. A **frequency** is the number of cycles (oscillations) per second of a radio signal.

Base Station Radios

The dispatcher usually communicates with field units by transmitting through a fixed radio base station that is controlled by the dispatch center. The **base station** is any radio hardware containing a transmitter and a receiver located in a fixed place. The base station may be used in a single place by an operator speaking into a microphone that is connected directly to the equipment. It also works remotely through telephone lines or by radio from a communications center. Base station locations may include dispatch centers, fire stations, ambulance bases, or hospitals.

Base station radios usually have more power (often 100 watts or more) and higher, more efficient antenna systems than mobile or portable radios. The increased broadcasting range allows the base station operator to communicate with field units and other stations at much greater distances.

The base station radio must be physically close to its antenna, unless it is a digital system. Therefore, the actual base system cabinet and hardware are commonly found on the roof of a tall building or at the bottom of an antenna tower. The antenna system has a vital part in transmission and reception efficiency. The base station operator may be miles away in a dispatch center or hospital, communicating with the base station radio by dedicated lines or special radio links.

A **dedicated line**, also known as a hotline, is used for specific point-to-point contact within a base station system. This type of phone, which is typically located within an ED, is not on the main switchboard. EMS personnel are able to call the number directly without being placed on hold or transferred. Generally, once the handset is lifted, the phone on the opposite end rings. This type of line makes contacting and recording medical command conversations much easier.

Mobile and Portable Radios

Once you leave the station, you will use both mobile and portable radios to communicate with the dispatcher and/or medical control. A **mobile radio** is mounted inside a vehicle. An ambulance will often have more than one mobile radio—one in the front and a second in the patient compartment—for communicating patient information to medical control. A mobile radio usually operates at lower

power than a base station (20 to 50 watts). It is also assigned to a specific radio frequency band. Certain frequency bands are more suitable for use under specific conditions.

Mobile transmitters/receivers, or transceivers, come in a variety of power ranges. The power output largely determines the distance over which the signal can be effectively transmitted. A transmitter in the 7.5-watt range, for example, will transmit for distances of 10 to 12 miles (16 to 19 km) over slightly hilly terrain. Transmission distances are greater over water or flat terrain and reduced in mountainous areas or where there are many tall buildings. Mobile transmitters with higher outputs have proportionally greater transmission ranges, making them useful, for example, in disaster situations where mobile units are in use. Today, the typical mobile transmitter operates at between 20 and 50 watts of power output.

Frequency bands are portions of the radio frequency spectrum assigned for specific uses. The most commonly used bands for medical communications are the **very high-frequency (VHF) band** and the **ultra high-frequency (UHF) band**. The VHF band extends from roughly 30 to 300 MHz. VHF has been arbitrarily divided into a low band (30 to 50 MHz) and a high band (132 to 174 MHz).

Words of Wisdom

VHF low-band frequencies may have ranges up to 2,000 miles (3,219 km) but are unpredictable because changes in ionospheric (about 30 miles [about 50 km] into the atmosphere) conditions may cause “skip interference,” with patchy losses in communication. The high-band frequencies are almost wholly free of skip interference, but have a much shorter transmission range. The most commonly used VHF high-band frequencies for emergency medical purposes are in the 150- to 160-MHz range. This has historically been the main radio band assigned by the FCC.⁸

In the late 1970s, the UHF band was assigned to EMS in the form of the MED channels. The UHF band extends from 300 to 3,000 MHz, with most medical communications occurring around 450 to 470 MHz. At these frequencies, communications are entirely free of skip interference and have minimal noise (ie, signal distortion). The UHF band has

better penetration in dense metropolitan areas, and UHF reception is usually quite adequate inside buildings. The UHF band, however, has a shorter range than the VHF band, and energy at UHF frequencies is more readily absorbed by rain and environmental objects, such as trees and brush.

A **portable radio** is a handheld, two-way radio with a limited range and low power (1 to 5 watts). These radios are carried by EMS providers when they are away from the vehicle (**FIGURE 4-8**). Portable units may also be used by physician consultants when not stationed at the hospital.

Radios that operate at 800 MHz (also known as trunked systems, discussed later) are also becoming increasingly common in EMS systems. This frequency offers excellent penetration of buildings and has minimal interference and reduced channel noise. Mobile antennas are much closer to the ground than base station antennas, so communications from the unit are typically limited to 10 to 15 miles over average terrain.

Assigned radio frequencies may be used in a variety of systems. In a **simplex** (push to talk, release to listen) system, or half-duplex system, portable units can transmit in either direction but not simultaneously in both. When one party transmits, the other can only receive. A simplex system requires only a single radio frequency. A network that uses two different frequencies at the same time to permit simultaneous transmission (talk) and reception (listen) (like a telephone) is referred to as **duplex**. In the full duplex mode, radios can simultaneously transmit and receive communications on

FIGURE 4-8 A portable radio is essential if you need to communicate with the dispatcher or medical control when you are away from the ambulance.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

one channel—an approach sometimes called a pair of frequencies. **Multiplex** communications (combining both analog and digital signals) can simultaneously transmit two or more different types of information, such as voice and telemetry, in either or both directions over the same frequency. As noted earlier, certain VHF and UHF channels, commonly called **MED channels**, are reserved exclusively for EMS use. However, hundreds of other commercial, local government, and fire services frequencies are also used for EMS communications.

Repeater-Based Systems

A **repeater** is a special radio station that receives messages and signals on one frequency and then automatically retransmits them on a second frequency (**FIGURE 4-9**). A repeater is an automated radio station (with a large antenna) that is able to receive lower-power signals, such as those from a portable radio, from a long distance away. The signal is then rebroadcast with all the power of the base station. EMS systems that use repeaters usually have outstanding systemwide communications and are able to get the best signal from portable radios. Mobile repeaters may also be found in ambulances or placed in various areas around an EMS system area.

At times, you may be able to communicate with a base station radio, but you will not be able to hear or transmit to another mobile unit that is also communicating with that base. Repeater base stations eliminate such problems. They allow two mobile or portable units that cannot reach each other directly to communicate through the repeater, using its greater power and antenna.

FIGURE 4-9 A message is sent from the control center to the transmitter by a landline. The radio carrier wave is picked up by the repeater for rebroadcast to outlying units. Return radio traffic is picked up by the repeater and rebroadcast to the control center.

Digital Radio and Trunked Systems

Digital radio may help clear up distorted or lost transmissions, which are always possible with base station, mobile, and portable radio communications. **Digital radio** systems allow the transmission of digital signals (computer) or analog (voice) signals that have been digitized and compressed by a computer. Digital signals are clearer and allow the transmission of a greater volume of data in the same bandwidth. Digital radios can communicate with other digital radios and with analog radios. Conventional radios operate on fixed radio frequency channels. When radios have multiple channels, they operate on one channel at a time and the proper channel is selected by a user; that is, the user picks the channel by using a channel selector or pressing a button on the radio control panel.

With digital **trunked radios**, either 800- or 900-MHz systems, instead of being assigned to one or two frequencies, many frequencies are assigned to a group. These groups can be thought of as virtual channels that appear and disappear as conversations occur. As a radio conversation begins, a computer selects or *scans* for the next open frequency and you can begin talking. When you speak a second time, you will likely be speaking on a different frequency because the computer is constantly monitoring for frequency load and reassigning transmissions to unused frequencies. These systems allow for greater traffic without greater numbers of frequencies. Therefore, you do not need to worry about being able to transmit or receive. In a trunking system, the computer will switch you to another channel without your knowledge and you will operate the radio as you normally do.

Concerns Related to Radio Communication

Your ability to effectively communicate with other units or medical control via radio depends on how well the weaker radio can “talk back.” Base and repeater station radios often have higher antennas and much greater power than mobile or portable units do. This increased power ensures that signals are generally heard and understood from a far greater distance than the signal produced from a mobile unit. Remember, when you are at the scene, you may be able to clearly hear the dispatcher or

hospital on your radio, but you may not be heard or understood when you transmit.

Even small changes in your location can significantly affect the quality of your transmission. Also remember that the location of the antenna is critically important for clear transmission. Commercial aircraft flying at an altitude of 37,000 feet (11 km) can transmit and receive signals over hundreds of miles, yet their radios have only a few watts of power. The “power” comes from their antenna positioned at 37,000 feet.

The success of communications depends on the efficiency of your equipment. A damaged antenna or microphone often prevents high-quality communications. Check the condition and status of your equipment at the start of each shift, and then correct or report any problems.

Maintenance of Radio Equipment

Like all other EMS equipment, radio equipment must be serviced by properly trained and equipped personnel. Remember, the radio is your lifeline to other public safety agencies (which function to protect you), as well as medical control, and it must perform under emergency conditions. Radio equipment that is operating properly should be serviced at least once per year. Any equipment that is not working properly should be immediately removed from service and sent for repair. Outdated equipment should be immediately removed from service as new equipment becomes available.

When you are beginning your shift, it is typical to check the ambulance to ensure it is ready to go. You cannot assume the crew before you left the ambulance well stocked and in operational readiness. The radio is also an important component that needs to be checked to ensure that it is operating correctly and using the correct frequency.

Maintaining radio equipment will also help to ensure efficient, effective communication and ensure the radio is not drifting from its assigned frequency. If possible, do not subject radio equipment to dusty, damp, or wet environments. Frequent cleaning of radio equipment will improve its appearance as well as life expectancy. Follow the manufacturer’s directions for cleaning specific equipment.

Properly used, rechargeable batteries in portable radios and other equipment will maximize life

and power output. Ensure you recharge batteries as needed. Finally, familiarize yourself with the manufacturer's instructions for each piece of equipment you are using.

Cell/Satellite Telephones

Although it is common for dispatchers to communicate with field units by transmitting through a fixed radio base station, it is common for providers

Words of Wisdom

Since the introduction of smartphones, EMS communication has been greatly enhanced. Not only is a cell phone convenient for calling medical control or a supervisor, but it also provides a wealth of knowledge at the touch of a button. Global positioning system (GPS) receivers and mapping software are excellent resources in unfamiliar territories. Translating apps are available for almost any language you may encounter; written or verbal translations make it much easier to care for a non-English-speaking patient. There are also many apps created especially for medical personnel and EMS personnel, such as pharmaceutical references and EMS field guides at every level. Many services have even created apps or Internet links to local protocols.

Remember the saying "A picture is worth a thousand words"? Think how valuable a quick photo of the extensive damage to a vehicle and the resulting size of the patient compartment may be to a trauma surgeon who is receiving a patient from that particular crash. Photos of injuries might also be sent ahead to the ED in preparation for patient arrival. Video conferences (such as telemedicine or the use of video conferencing apps) between medical control and the reluctant patient may be the push needed to convince the person to accept treatment and transport. However, you must never infringe on a patient's privacy. Any photos or videos taken should be shown or sent only to those personnel who are providing care for the patient and then promptly deleted. Do not use an unsecure WiFi source to transmit information. Another option is a satphone, or satellite phone. These phones use a satellite, which receives and relays the signals, instead of a cellular system. Satellite telephones and messaging devices can be valuable in rural and remote areas with spotty or absent radio and cell phone coverage. They are also an invaluable resource in disaster situations. However, this technology is expensive, compared to the alternatives that exist, which can limit its accessibility.

to communicate to receiving facilities by **cell phone**. These telephones are simply low-power portable radios that communicate through a series of interconnected repeater stations called cells. Cells are linked by a sophisticated computer system and connected to the telephone network. Not all EMS services allow the use of cell phones for reports or contacting medical control.

Many cellular systems make equipment and air time available to EMS at little or no cost as a public service. The public is often able to call 9-1-1 or other emergency numbers on a cell phone free of charge. However, this easy access may result in overloading and jamming of cellular systems in MCIs and disaster situations, and you should have a backup communications plan in your service to circumvent these overloads.

As with all repeater-based systems, a cell/satellite telephone is useless if the equipment fails, loses power, or is damaged by severe weather or other circumstances. Because these telephones use digital signals, eavesdropping on communication shared through these devices is difficult—but not impossible.

Digital Equipment

The term *biotelemetry* in emergency medical care is usually shortened to *telemetry*. **Telemetry** is the capability of measuring vital life signs and transmitting these data to a distant terminal. Telemetry started with electrocardiograms (ECGs), but now often includes other measurements. Even the US space program uses telemetry to send pulse and respiratory rate data for astronauts from space to a receiving station on earth.⁹

Most often, telemetry is a short way of saying that you are transmitting an ECG signal from the patient to a distant receiving station. The standard ECG is composed of low-frequency signals (100 Hz or less), which would be filtered out by a voice communications system. To ensure voice communication does not filter out the ECG, the ECG signal must be **encoded** if it is to be sent over the same radio channels used to transmit voice. ECG telemetry over UHF frequencies is confined to one lead of a 12-lead ECG, so it can be used to interpret cardiac rhythms. For a more complete diagnosis of an ECG, such as in the case of examining the ECG of a patient with suspected acute coronary syndrome,

the information from all 12 leads of the ECG must be examined.

New technology also allows for digital telemetry. For example, data from cardiac monitors can be transmitted via Bluetooth-enabled mobile devices to a monitoring center, where physicians can review the data quickly and give further orders if needed. Most cardiac monitors used on ambulances today have the technology to transmit 12-lead ECGs directly to the ED where the patient is being transported. Digital signals are also used in some kinds of paging and tone alerting systems because they transmit faster than spoken words and allow more choices and flexibility.

Distortion of the ECG signal by extraneous spikes and waves (noise) may arise from a variety of sources:

- Muscle tremor
- Loose ECG electrodes
- Sources of 60-cycle alternating current (AC), such as transformers, power lines, and electric equipment
- Attenuation (reduction) of transmitter power, caused by weak batteries or transmission beyond the range of the transmitter

Other Communications Equipment

Interoperability

Any large-scale emergency requires cooperative efforts from several agencies such as law enforcement, fire departments, and EMS. At times, more than one jurisdiction is involved and effective communication among all of those involved becomes challenging. Due to difficulties arising from incompatible communications systems, there is a push for interoperability—compatibility of an agency's communications system with that of another agency. An **interoperable communications system** allows all agencies involved to share valuable information with each other in real time. This system utilizes voice-over-Internet-protocol (VoIP) technology to connect landlines, cell phones, and computers to create a seamless, reliable exchange of information among all parties.

The US Department of Homeland Security developed the SAFECOM communications program, a set of national interoperability standards intended

to develop compatibility across communications systems, whether local, state, or federal. An important part of these interoperability standards is the use of nationally standardized frequencies for disasters and other communications. Each state has also established its own internal standards for interoperability between local jurisdictions.

In addition, the Association of Public-Safety Communications Officials-International has established digital radio hardware standards, known as the Project 25 (P25) standards, to ensure digital radio equipment manufacturers develop systems that are compatible with each other, and with older systems that may still be in use.

Words of Wisdom

Public safety agencies must place greater importance on how they use technology and how it enhances the ability to protect and serve.¹⁰ Public safety communications channels are available for listening on the Internet or are openly broadcast, giving the public, media, criminals, and potential terrorists immediate access to information. While public safety agencies must work together to enhance interoperability, they must also respect the need to protect critical communications from compromise. Failure to do so may result in a delay in emergency response, an impedance of investigations or surveillance, and endangerment to the public.

Encryption (scrambling of data so that only those with a key can understand it) of information transmitted via public safety radios may be the best way to protect critical information transmitted over the airwaves.¹¹ However, encryption can be an issue if responding agencies do not have the key and therefore cannot hear the broadcast. Although encryption is common for federal agencies, state and local governments must consider the costs of implementation, the associated complex legal issues, and the question of who will have access. Then they must weigh these costs against the risks associated with exposure of sensitive information.

Computer-Aided Dispatch

Digital systems may also communicate text from **computer-aided dispatch (CAD)**. Ambulances are equipped with vehicle locators that allow the computer to “see” the location of each ambulance. A CAD system is a computerized method of call handling in which a computer collects and manages

the call information and makes recommendations for which EMS unit is closest based on existing dispatch policy. As it does this, the data for dispatch can be sent directly to the individual EMS unit by data transfer if the unit has an MDT. The result is that the EMS unit will see what is seen on the CAD terminal. For example, a display in an ambulance might give a textual location for a call and any related details, including mapping and directions to a call. When the driver presses an acknowledge button, data are sent in the opposite direction and the call is flagged as having been received by the driver. The entire dispatch and call response information exchange is visible on the mobile display.

In addition to managing call dispatch and location information, the CAD can recommend emergency actions to the dispatcher for relay to the patient or bystanders at the emergency scene. Such **prearrival instructions** allow care to begin even before the ambulance arrives on the scene. The CAD operator has access to emergency aid information relating to almost every possible EMS-related emergency. These protocols are typically developed by a major supplier and then reviewed by a physician. On installation, the protocols must then be reviewed and approved by local medical direction and the EMS system.

FIGURE 4-10 A mobile data terminal.

© Jones & Bartlett Learning. Courtesy of Paul W. Dow.

Mobile Data Terminals

Another type of communications system becoming popular is the **mobile data terminal (MDT)** (**FIGURE 4-10**). An MDT is a small computer terminal inside an ambulance that directly receives data from the dispatch center. An MDT allows for greatly expanded communication capabilities. Instead of having to listen to the dispatcher and determine whether he said 11345 Main Street or 11354 Main Street, you look at the terminal where the address is displayed and obtain directions. An MDT may

YOU are the Provider

Part 3

Using verbal techniques, you and the officers are able to calm the friends, and the officers walk the friends to the opposite side of the yard in an attempt to keep them away from the patient. You ask her if she would like to be transported to the ED. She replies, "I guess it's not that bad; I would just like to stay here." On the basis of local protocols requiring medical control approval for any patient refusals, you contact your medical control for permission to obtain a refusal of care. Next, you ask the patient to wash the injury and apply a bandage to the laceration on the patient's arm.

Recording Time: 8 Minutes

Respirations	16 breaths/min

6. Does this patient have the right to refuse transport to the hospital?

also allow for communication without the use of the radio. For example, providers can press a button on the MDT that corresponds with *en route* or *on scene*, to communicate their acknowledgment to dispatch. Satellite communications can track your progress to the scene via GPS mapping and can provide important scene information, such as known violent calls to this address, the nature of those calls, and the number of times the ambulance has been called.

Backup Communications Strategies

Sometimes, radio equipment will stop working during a run. Your EMS system must have several backup plans and options. The goal of a backup plan is to ensure you can maintain contact when the usual procedures do not work. There are quite a few options.

The simplest backup plan relies on written standing orders. **Standing orders** are written documents that have been signed by the EMS system's medical director. These orders outline specific directions, permissions, and sometimes prohibitions regarding patient care. By their very nature, standing orders do not require prior communication with medical control. When properly followed, standing orders or formal protocols have the same authority and legal status as orders given over the radio. They exist in every EMS system and can be applied to all levels of EMS providers.

In addition to radio communications, most EMS systems use **landline** (telephone) backup to link various fixed components of their communications system, such as hospitals, public safety services, and poison control. Telephones may also be patched into radio transmissions through the base station or via 9-1-1 dispatch.

Moreover, as mentioned earlier, cell phones are becoming an increasingly important part of EMS communications, overcoming many of the problems associated with the overcrowded EMS radio frequencies. Cell phones are less expensive than radios and generally give a much clearer signal. Furthermore, they enable an AEMT in the field to communicate with anyone who has a telephone—for example, the patient's family physician, an injured child's parent, or an expert in another state who can advise on a hazardous materials situation. The limitations of using cellular communications

as a backup or even a primary form of communications become most readily apparent in disasters. If a disaster affects your primary communications system (eg, through widespread power outages or tower damage), then the cell towers may be affected as well. In addition, the cell sites may be overwhelmed with civilian traffic. The cellular computer that assigns channels will not recognize an AEMT's phone and give it priority over another user's phone, so you may face delays in getting a channel. Some cellular providers are beginning to designate specific cellular bandwidths for first responder use to help mitigate this issue.

Older low-band and high-band simplex systems that are still licensed and maintained just for redundancy may also prove invaluable. In the case of disasters or power failures, older systems can still transmit and receive because most base stations have generators and EMS units operate off batteries. Because no power supply is necessary at a cell site or repeater site miles away, the older radios continue to allow communication.

The EMS Communication Process

The verb “to dispatch” means “to send out on a mission,” but the **emergency medical dispatcher (EMD)** does a lot more than just send ambulances out to emergencies. The EMD functions as a vital part of the EMS team who obtains as much information as possible about the emergency, then directs the appropriate vehicle to the scene, and provides the caller with whatever advice may be needed to manage the situation until help arrives. The EMD also monitors and coordinates communication with the field and maintains written records pertaining to the response to the call.

Notification

The first stage of EMS response is notification; that is, someone has to tell EMS that an emergency exists. Usually, notification is carried out by telephone or cell phone, and the person requesting help communicates with the EMD (**FIGURE 4-11**). A universal emergency telephone number (9-1-1 in the United States) and the availability of telephones and cell phones in most places has greatly helped notification. Notification may, less frequently, come by

FIGURE 4-11 The dispatcher receives the first call to 9-1-1.

© Jones & Bartlett Learning, Courtesy of MIEMSS.

radio, when the emergency is detected by a law enforcement or other public vehicle.

When the first call to 9-1-1 comes in, the dispatcher must judge its relative importance to begin the appropriate EMS response using emergency medical dispatch protocols. First, the dispatcher must find out the exact location of the patient and the nature and severity of the problem. The dispatcher asks for the caller's telephone number, the patient's name and age, and other information, as directed by local protocol. Next, the dispatcher asks for some description of the scene, such as the number of patients or special environmental hazards.

From this information, the dispatcher will assign the appropriate EMS response unit or units on the basis of local protocols to determine the level and type of response and the following factors:

- The dispatcher's determination of the nature and severity of the problem (Many emergency medical dispatch systems will determine this automatically based on a caller's answers to a defined series of questions.)
- Anticipated response time to the scene
- Level of training (EMR, EMT, AEMT, paramedic) of available EMS response unit or units
- Need for additional EMS units, fire suppression, rescue, a hazardous materials team, air medical support, or law enforcement

Information about such hazards enables the EMD to contact other agencies that may have to be involved, such as utility workers to take care

of downed wires. In most modern dispatch centers, the EMD has visual prompts with the key questions to ask on the computer screen. In services equipped with **enhanced 9-1-1**, much of the call information—such as the phone number and location of the caller—is recorded automatically, and the EMD just needs to confirm the information on the screen.

Dispatch

The next step is dispatch, communicating from the service headquarters with the responding EMS team. The appropriate crew is contacted and informed of the nature of the call and its exact location. The dispatcher may use the dispatch radio system to contact units that are already in service and monitoring the channel. Dedicated lines (hotlines) between the control center and the EMS station may also be used.

The dispatcher may also page EMS personnel. Pagers are commonly used in EMS operations to alert on-duty and off-duty personnel, and in many cases are simulcast with radio transmissions. **Paging** involves the use of a coded tone or digital radio signal and a voice or display message that is transmitted to pagers (beepers) or desktop monitor radios with display screens. Paging signals may be sent to alert only certain personnel, or they may be blanket signals that will activate all the pagers in the EMS service. Pagers and monitor radios are convenient because they are usually silent until their specific paging code is received. Alerted personnel contact the dispatcher to confirm the message and receive details of their assignments. This step is eliminated when pages and radio transmissions are simultaneous. For example, personnel may acknowledge the transmission via radio without the need to verbally verify addresses (because they are available on the pager). Additional information may also be sent to the pager instead of over the radio. This is especially helpful when information is sensitive or radio traffic is particularly heavy.

Once EMS personnel have been alerted, they must be properly dispatched and sent to the incident. Every EMS system should use a standard dispatching procedure. The dispatcher should give the responding unit or units the following information:

- Nature and severity of the injury, illness, or incident

- Exact location of the incident
- Number of patients
- Responses by other public safety agencies
- Special directions or advisories, such as adverse road or traffic conditions, severe weather reports, or potential scene hazards
- Time at which the unit or units are dispatched
- Any additional pertinent information gathered, such as the potential for exposure to infectious diseases

Your unit must confirm with the dispatcher that you have received the information and are en route to the scene. Local protocol will dictate whether it is the job of the dispatcher or your unit to notify other public safety agencies that you are responding to an emergency. In some areas, the ED is also notified when an ambulance responds to an emergency.

While en route to and from the scene, you should report to the dispatcher any special hazards or road conditions that might affect other responding units. Report any unusual delay, such as roadblocks, traffic, or construction.

You should inform the dispatcher when you have arrived at the scene. The arrival report to the dispatcher should include any obvious details that you see during scene size-up. For example, you might say, “Dispatcher, BLS Unit Two is on scene at 381 Mitchell Street. It is a blue house with long driveway.” This information is particularly useful if additional units are responding to the same scene. You should also report to the dispatcher any problems during your response.

Words of Wisdom

Some agencies use a *tiered response system*. Initially, one unit responds to a scene and determines which resources are needed, which may be, for example, a higher level of training or a unit capable of transport. The dispatcher then sends the appropriate unit or units. This system frees up units and ensures that resources are allocated appropriately.

En Route Communications

Once the ambulance is dispatched, the EMD may return to the telephone to obtain further information from the original caller. Further questioning may reveal special conditions that might affect your team’s travel to a scene or actions at the scene. The

EMD will relay that information to you while you are en route, to prepare you to respond effectively. Conversely, you may need to contact the dispatcher to request additional resources.

If the dispatcher suspects the patient has a life-threatening emergency, then the dispatcher should also use simple terms to provide prearrival instructions to the caller. These prearrival instructions include explaining to the caller how to perform procedures such as bleeding control and CPR until help arrives. Some dispatch centers have trained EMS providers to relay basic medical instructions to callers when needed. The caller is likely to be in an agitated state, so instructions must be clear and simple. Such prearrival instructions give your service what many in EMS call “zero response time,” providing immediate aid and assistance, which can be vital in saving a life. Simple but life-saving acts such as clearing an obstructed airway, performing chest compressions, or reassuring the patient, can be performed by a layperson under the instructions of a good dispatcher. In many cases, these prearrival instructions may bring a sense of emotional support to a caller in a time of great need, reassuring people close to the patient that everything that can be done is being done.

Once the patient is ready to be moved, you must communicate with the receiving facility to let the hospital know what to expect. During transport, you must periodically reassess the patient’s overall condition, vital signs, and response to care provided. You should immediately report any significant changes in the patient’s condition, especially if the patient seems worse. This allows medical control to issue new orders and to prepare to receive the patient.

Some services have wireless systems that transmit the data in the PCR to the ED as the ambulance is pulling into the hospital’s parking lot. Once back at their stations, the AEMTs can transmit the PCR, and any additional documents specific to their department, to the service’s computer system.

TABLE 4-7 summarizes instances when EMS providers communicate with dispatch.

Communicating With Medical Control and Hospitals

The principal reason for radio communication is to facilitate communication between you and medical control (and the hospital). Medical control may be

TABLE 4-7 Typical EMS Communications With Dispatch

Phase of EMS Call	EMS Unit Communication
Initial receipt of call	Acknowledge call. Respond to the call.
En route to call	Request assistance with directions, when needed. Request additional resources, when needed.
On scene	Report arrival at scene. Check in; EMS systems will often require units to transmit at specified intervals as a safety measure. Request additional resources, when needed. Report when leaving the scene.
Arrival at hospital (or point of transfer)	Notify dispatch of arrival at point of transfer.
Return to service	Notify dispatch when the unit is available for another call.
Others	Some systems require EMS units to notify dispatch any time they are not in the station.

Abbreviation: EMS, emergency medical services

© Jones & Bartlett Learning.

located at the receiving hospital, another facility, or sometimes even in another city or state. You must consult with medical control to request advice or orders or to advise of special situations such as an entrapped patient with serious injuries that will require specialized care.

It is important to plan and organize your radio communication before you push the transmit button. Remember, a concise, well-organized report demonstrates your competence and professionalism in the eyes of all who hear your report. Well-organized radio communications with the hospital will engender confidence in the receiving facility's physicians and nurses, as well as others who are listening. In addition, the patient and family will be comforted by your organization and ability to communicate clearly. A well-delivered radio report puts

FIGURE 4-12 The patient report should be given in an objective, accurate, professional manner.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

you in control of the information, which is where you need to be.

Hospital notification is the most common type of communication between you and the hospital. The purpose of these calls is to notify the receiving facility of the patient's complaint and condition (**FIGURE 4-12**). On the basis of this information, the ED is able to appropriately prepare staff and equipment to receive the patient.

The Verbal Radio Report

The verbal radio report or patient report should follow the standard format established by your EMS system. It commonly includes the following elements:

1. The receiving hospital, your unit identification, level of certification, and status of transport. Example: "Columbus Community Hospital, this is Med 2, AEMT Smythe and AEMT Jennings, en route to your facility emergency status."
2. The patient's age, sex, and approximate weight (if needed for drug orders). Example: "We are en route to your facility with a 15-year-old adolescent male, approximately 50 kg." The patient's name should not be given over the radio because it may be overheard. This could be a violation of the patient's confidentiality.

3. Description of the scene. Example: “Patient was playing on a neighbor’s trampoline when he jumped off the one-story garage onto the trampoline. From there he bounced off and landed on his head and shoulders.”
4. The patient’s level of consciousness, chief complaint or your perception of the problem, and its severity and associated symptoms. Example: “The patient is alert and oriented times three, denies any loss of consciousness, but stated he had the wind knocked out of him. Complains of numbness and tingling in all four extremities.”
5. A brief, pertinent history of the patient’s present illness or injury. Example: “The patient has a history of epilepsy and takes Dilantin. He says he takes it daily, but forgot to take it today.”
6. A brief report of physical findings. This report should include the patient’s general appearance, degree of distress, pertinent abnormalities noted, and baseline vital signs. Example: “The patient is pale, cool, and diaphoretic. Complains of numbness and tingling in all four extremities. BP is 78/32, pulse is 116, and respirations are 20.”
7. A brief summary of the care given and any patient response. Example: “We have immobilized him on a long backboard. PMS in the extremities are intact. We initiated an IV bolus of normal saline and patient is on oxygen via nonrebreathing mask at 15 L/min.”
8. Any other pertinent information and the estimated time of arrival (ETA). Example: “Patient’s physician is Kip Anderson. ETA is 4 minutes.”
9. Determine whether the receiving facility has any additional questions or orders.

Ensure you report all patient information in an objective, accurate, and professional manner (**TABLE 4-8**). Keep in mind that scanners may be used to monitor radio traffic. Stick to the pertinent facts of the report to avoid HIPAA violations as well as an invasion of patient privacy.

The Role of Medical Control

The delivery of EMS involves an impressive array of assessments, stabilization, and treatments. AEMTs may initiate medication therapy based on

TABLE 4-8 Verbal Radio Report

- Identify destination facility - Unit name and number - Crew and level of certification - Status of transport (emergency/nonemergency)
- Patient’s age - Patient’s sex - Level of consciousness
Chief complaint or primary problem
- Description of scene - General appearance
Brief history of present illness/injury
- Associated signs/symptoms - Pertinent negatives - Degree of distress
- Vital signs - Blood pressure - Pulse - Respirations - Skin - Glucose level - Pulse oximetry
- Neurologic exam - Pulse, motor, sensation in extremities - Pupillary response
Past pertinent medical history
Secondary assessment findings
- Any treatment provided - Response to treatment (favorable/unfavorable)
Any request for treatment
Name of personal physician (if appropriate)
Estimated time of arrival

the patient’s presenting signs. For logical, ethical, and legal reasons, the delivery of such sophisticated care must be done in association with physicians. For this reason, every EMS system needs input and involvement from physicians. One or more physicians, including your system or department medical director, will provide medical direction (medical control) for your EMS system. Medical control is either off-line (indirect) or online (direct), as authorized by the medical director. Medical

control guides the treatment of patients in the system through protocols, direct orders and advice, and post-call review.

Depending on how your system's protocols are written, you may need to call medical control for direct orders (permission) to administer certain treatments, to determine the transport destination of patients, or to be allowed to stop treatment and/or transport of a patient. In these cases, the radio or cell phone provides a vital link between you and the expertise available through the base physician.

To maintain this link 24 hours per day, 7 days per week, medical control must be readily available on the radio at the hospital or on a mobile or portable unit when you call. In most areas, medical control is provided by the physicians who work at the receiving hospital. However, many variations have developed across the country. For example, some EMS units receive medical direction from one hospital even though they are taking the patient to another hospital. In other areas, medical direction may come from a free-standing center or even from an individual physician. Regardless of your system's design, your link to medical control is vital to maintain the high quality of care that your patient requires and deserves.

Calling Medical Control

You can use the radio in your unit or a portable radio to call medical control. A cell phone can also be used for this purpose. Regardless of the type of communication, you should use a channel that is relatively free of other radio traffic and interference and one that will be recorded. Medical command communications create medicolegal requirements that such conversations should be recorded. There are several ways to control access on ambulance-to-hospital channels. In some EMS systems, the dispatcher monitors and assigns appropriate, clear medical control channels. Other EMS systems rely on special communications operations, such as a CMED (Centralized Medical Emergency Dispatch) or resource coordination centers, to monitor and allocate the medical control channels.

Because of the large number of EMS calls to medical control, your radio report must be well organized, be precise, and contain only pertinent information. In addition, if you are requesting orders

for patient care, the information that you provide to medical control must be accurate, concise, and yet sufficient to communicate the need for the treatment for which you are requesting authorization. Remember, the physician on the other end bases instructions on the information that you provide.

You should never use codes when communicating with medical control unless you are directed by local protocol to do so. Instead, use proper medical terminology when giving your report. Never assume medical control will know what a "10-50" or "Signal 70" means. Most medical control systems handle many different EMS agencies and will most likely not know your unit's special codes or signals.

To ensure complete understanding, once you receive an order from medical control, you must repeat the order back, word for word, and then receive confirmation that your understanding is correct. This "echo" exchange helps to eliminate confusion and the possibility of poor patient care. Orders that are unclear or seem inappropriate or incorrect should be questioned. Do not blindly follow an order that does not make sense to you. The physician may have misunderstood or may have missed part of your report. In that case, the physician may not be able to respond appropriately to the patient's needs.

Words of Wisdom

When contacting medical control for orders, always "echo" the orders back to the physician to avoid misunderstandings. If an order is not clear or seems inappropriate, then ask for clarification, repeating vital signs and other information as needed.

Information About Special Situations

Depending on your system's procedures, you may initiate communication with one or more hospitals to advise them of an extraordinary call or special situation. For example, a small rural hospital may be better able to respond to multiple victims of a highway crash if it is notified when the ambulance is first responding. At the other extreme, an entire hospital system must be notified of any disaster, such as a plane or train crash, as early as possible to enable activation of its staff call-in system. These situations might also include hazardous materials

(hazmat) scenes, rescues in progress, MCIs, or any other situation that might require special preparation on the part of the hospital. In some areas, mutual aid frequencies may be designated in MCIs so that responding agencies can communicate with one another on a common frequency.

It is also important to notify the receiving hospital of the need for specialty items. For example, if you are transporting a ventilator-dependent patient from home and providing bag-mask ventilations, then call the hospital prior to disconnecting the patient from their own ventilator to ensure the receiving facility has a ventilator available on your arrival.

When notifying the hospital or hospitals of any special situations, keep the following in mind: the earlier the notification, the better. You should ask to speak to the charge nurse or physician in charge, as this person is best able to mobilize the resources necessary to respond. Also, whenever possible, provide an estimate of the number of people who may be transported to the facility. Ensure you identify any conditions the patient or patients might have that require special resources, such as burns or hazmat exposure, to assist the hospital in preparation. In many cases, hospital notification is part of a larger disaster or hazmat plan. Follow the plan for your system.

Effective Radio Communications

You must use your radio communications system effectively from the time you acknowledge a call until you complete your run. Standard radio operating procedures are designed to reduce the number of misunderstood messages, to keep transmissions brief, and to develop effective radio discipline. Standard radio communications protocols help both you and the dispatcher to communicate properly (**TABLE 4-9**). Protocols should include guidelines specifying a preferred format for transmitting messages, definitions of key words and phrases, and procedures for troubleshooting common radio communications problems.

Words of Wisdom

Seek clarification for any orders you did not hear clearly or did not understand.

TABLE 4-9 Guidelines for Effective Radio Communication

Turn on the radio and adjust the volume.
Ensure a clear frequency and minimal noise before speaking.
Monitor background noise. If you are in transit, then shut off the siren when possible. Plan your message to keep your transmissions brief and precise.
Use the standard format for transmission of information.
To speak, use the “press-to-talk” (PTT) button, and wait for 1 second before speaking.
Hold the microphone 2 to 3 inches (5 to 7 cm) from your mouth.
Address the unit or hospital you are calling, and provide the name of your unit.
Wait for the signal that you can begin your transmission.
Use a clear, calm, monotone voice and speak at a reasonable pace.
Keep the transmission brief.
Use clear text.
Avoid the use of codes or agency-specific terms.
Use the words <i>affirmative</i> and <i>negative</i> instead of yes and no.
Limit saying “please,” “thank you,” and “you’re welcome.”
Do not use vague phrases such as be advised.
Do not use slang.
Never use profanity; always be professional.
When you are transmitting a number, such as an address, provide both the number and the individual digits. For example, “Respond to 381, 3-8-1, Main Street.”
Remember that the airwaves are public and the use of scanners is popular.
Use EMS frequencies only for EMS communications.
Ensure other radios on the same frequency are turned down to avoid feedback.
Remain objective and impartial in describing patients.
Do not provide a diagnosis of the patient’s problem.
Do not use names; protect the privacy of patients.

Abbreviation: EMS, emergency medical services

© Jones & Bartlett Learning.

Written Communications and Documentation

The PCR is the legal document used to record all aspects of the care the patient received, from initial dispatch to arrival at the hospital. A shortened report may be used as a record of transfer of care until the primary PCR can be completed. It should contain a minimum data set as well as a transfer signature.

You may be able to complete the written report en route to the hospital if the trip is long enough and the patient needs minimal care. Your goal should be to provide a report prior to departing from the hospital. Usually, you will finish the written report after you have transferred the care of the patient to an ED staff member. There are two types of PCRs: written and electronic (ePCRs), which will be discussed later in this chapter.

The information you collect during a call becomes part of the PCR, and that information is ultimately entered into a data pool. The National Emergency Medical Services Information System (NEMSIS; nemsis.org) has been collecting patient care information for research purposes since the early 1970s. NEMSIS has identified specific data points (uniform components) needed to enable communication and comparison of EMS runs

between agencies, regions, and states. The minimum data set includes both narrative components and check-off boxes (**FIGURE 4-13**). You can see the national data set and discover interesting facts about the delivery of EMS within the United States at ems.gov.

Because some EMS systems track their own time, ensure your watch is set with dispatch time at the beginning of the shift, if that is your system's procedure. Another way you can manage this information is to contact the dispatcher and have the person provide you with the time. Either way, it is important to be able to keep close track of time. Accurate documentation will depend on it.

It is standard procedure to use 24-hour (military) time in EMS documentation. This ensures that each time is unique; for example, 1:00 am cannot be confused with 1:00 pm. Military times are shown in **TABLE 4-10**.

You will begin gathering the patient information as soon as you reach the patient. Continue collecting information as you provide care until you arrive at the ED.

You need to understand what constitutes documentation of a PCR, which information must be included, who might read the report, when the report must be completed, and which terminology may be

FIGURE 4-13 The minimum data set includes both patient information and administrative information.

TABLE 4-10 Military Times

Standard Time	Military Time	Standard Time	Military Time
Midnight	0000	Noon	1200
1:00 am	0100	1:00 pm	1300
2:00 am	0200	2:00 pm	1400
3:00 am	0300	3:00 pm	1500
4:00 am	0400	4:00 pm	1600
5:00 am	0500	5:00 pm	1700
6:00 am	0600	6:00 pm	1800
7:00 am	0700	7:00 pm	1900
8:00 am	0800	8:00 pm	2000
9:00 am	0900	9:00 pm	2100
10:00 am	1000	10:00 pm	2200
11:00 am	1100	11:00 pm	2300

© Jones & Bartlett Learning.

used. Learning to write effectively and accurately is an important AEMT skill.

Information may be categorized as objective or subjective. **Objective information** includes the measurable signs that you observe and record, such as blood pressure. **Subjective information** includes information that is told to you, but that cannot be seen, such as the patient's description of symptoms—the degree of pain, for example. You must record objective *and* subjective information and the details of patient care for every call in a written or computer-based report.

Every report needs to be complete, accurate, and legible, for numerous reasons. Your report should “paint a picture” of the entire call that is accurate and clear to the reader. It provides the basis for continuity of care by describing the initial presentation of the patient, treatment provided, and any changes. It can also provide the basis of defense in legal proceedings. It is of vital importance to your service or agency for many other reasons as well, such as for facilitation of quality care, development of protocols, and billing insurance.

Types of PCRs

EMS has entered an age in which electronic documentation has become the standard. Although

some services still use paper documentation, you will most likely document your emergency calls and other reports electronically. The many benefits of electronic documentation are discussed later in this section. Perhaps the most significant benefit is the ability for electronic data to be shared—not only between the facilities and personnel involved in a patient's care, thereby improving continuity and efficiency, but also among state and national databases to improve national data collection and further the advancement of evidence-based practice. While the features of ePCR software and services vary greatly, all are designed to comply with NEMSIS data collection requirements.

A multitude of PCR designs exist throughout the United States and range from half-page notes to complete and thorough reports. EMS patient care reporting has evolved over the years because the field of medicine has recognized the necessity for information about the patient's condition and interventions performed in the field. Some services have developed PCRs that nearly eliminate the narrative section and replace the space with either check boxes or dropdown menus with predetermined terms. You may encounter some reports that have hundreds of check boxes, allowing for you to mark every action you took. The problem with these types of reports is that the format

increases the risk of errors that may occur when your eyes become overwhelmed by so many check boxes and you accidentally select the wrong box. Regardless of what form of patient reporting your service may use, it is important that you obtain the proper information.

Paper reporting is becoming a thing of the past because it duplicates work done in other parts of the health care system. To fulfill EMS data collection requirements, handwritten reports must be entered into an electronic system, either by health care agencies or by separate companies to which this task has been outsourced. Along with the additional data entry needs, a paper system requires space to store the records, possibly for a lengthy period of time depending on state laws. ePCRs allow you to transmit patient information directly to hospital computers for review by the physician, pharmacy, and other professionals providing patient care and may be directly integrated with the patient's electronic medical record.

The final reason there has been a major shift away from paper reporting systems is the drive to reduce errors in documentation. Often, penmanship and spelling errors lead to medical mistakes when it comes to medication doses and orders; an electronic system minimizes these issues.

With today's technology, a multitude of companies have created a variety of ePCRs. These services range from scanning of paper forms to computer-based programs for desktops, tablets, laptops, and smartphones, allowing for a more accurate and legible report (**FIGURE 4-14**).

Modern data systems can incorporate data from various sources, such as multiple facilities. This feature is in line with the major effort on the part of hospitals and physicians to improve the quality of cardiac, stroke, and diabetic care, and improve the success of resuscitation efforts. Such cutting-edge systems will ultimately include EMS documentation so that the PCR contains both information from the field and further data from the hospitals or facilities where the patient was treated. The result will be one comprehensive record of the care the patient received.

To ensure data can be shared on a national level, electronic documentation systems should be NEMSIS compliant. As mentioned, data submission to NEMSIS is important for EMS research and to assess and improve EMS care throughout the country. The goal of NEMSIS is to facilitate submission

of EMS data from all states, and part of that process is to implement electronic documentation systems in all states. Today, most states and territories of the United States are either submitting electronic data to NEMSIS or are actively working toward achieving this goal in the near future.

Street Smarts

When using an electronic documentation system, be sure to review your report before submitting it. AEMTs often click through the check boxes and dropdown menus quickly, but it is essential that what is documented in this part of the electronic report match what is documented in the narrative. The check boxes should not indicate the patient is awake and alert to person, place, time, and location when you have documented in the narrative that the patient is confused and does not know where he is. This is an easy error to make, but is usually caught by quickly reviewing the report.

Legal Issues of a PCR

Although you may include subjective information from the patient, such as statements about symptoms, no bias or personal opinions (subjectivity) of your own should appear in your report. For example, rather than stating "the patient was drunk and out of control," your documentation might say, "the patient presented with an altered mental status and stated he had eight beers today." Poorly written, inappropriately documented PCRs could have adverse implications both for patient care and for your career. Omissions or errors in your report could lead to further errors in care. Improper and inadequate reports can also result in legal action, cause loss of job or position, have a negative impact on your reputation as an EMS professional, and have other unfortunate consequences.

No matter what your particular writing style is, your report should be complete, well written, legible, and professional, and it should be your sole source of information about the call, because it may be used in legal proceedings against you or someone else. In some cases, it may be your only defense against a complaint about a call: if you document what happened, then you will have solid evidence of your conduct and what transpired on the call. Your memory may not serve you well

FIGURE 4-14 A variety of software programs exist for creating electronic patient care reports, allowing EMS personnel to clearly document details of the call.

Courtesy of Rhonda Hunt; Courtesy of Jim Emerton; Provided with permission by Zoll Medical.

5 to 7 years from now, but your written report will remain as a record. If it is well written, then it will jog your memory and should clearly recall the events of the call for all who read it.

As a health care professional, it is important that you use proper spelling, proper grammar, and accurate terminology in your report. Do not attempt to use medical terms and abbreviations if you do not fully understand their meanings. Never make up your own abbreviations, because they will be meaningful only to you and could confuse others.

Components of a PCR

As discussed, a PCR helps ensure efficient continuity of patient care. This report describes the nature of the patient's injuries or illness at the scene and the treatment you provide. Although this report might not be read immediately at the hospital, it may very well be referred to later for important information. The report serves the following six functions:

1. Continuity of care
2. Legal documentation
3. Education
4. Administrative information
5. Essential research record
6. Evaluation and continuous quality improvement

Besides reporting the patient's condition on arrival at the scene and the care that was provided, a good PCR documents any changes in the patient's condition en route and on arrival at the hospital. It is critical that you document everything as clearly as possible, because the report serves multiple purposes. The information in the report will help to prove that you have provided a standard of care and, in some instances, shows you have properly handled unusual or uncommon situations.

The following are examples of patient information collected on a PCR:

- Chief complaint
- Level of consciousness (according to the AVPU [Awake and alert, responsive to Verbal stimuli, responsive to Pain, Unresponsive] scale) or mental status
- Vital signs
- Assessment findings
- Patient demographics (age, sex, ethnic background)

Typically, the person who completes the form is the one who goes to court. Should you ever be called to provide testimony concerning patient care, you and your PCR will be used to present evidence. As with your personal appearance, your PCR will reflect a professional or a nonprofessional image. A neat, concise, well-written document—including correct spelling and grammar—will reflect good patient care.

These reports also provide valuable administrative information. For example, the report provides information for patient billing. It can also be used to evaluate response times, equipment usage, and other areas of administrative responsibility. In addition, information gathered may be used to improve different components of the EMS system and prevent problems from occurring. The following are examples of administrative information gathered from a PCR:

- The time the incident was reported
- The time the EMS unit was notified
- The time the EMS unit arrived at the scene
- The time the EMS unit left the scene
- The time the EMS unit arrived at the receiving facility
- The time the patient care was transferred

Data may be obtained from the PCR to analyze causes, severity, and types of illness or injury requiring emergency medical care. These reports may also be used in an ongoing program for evaluation of the quality of patient care. Reports are periodically reviewed by your system. The purpose of these reviews is to ensure trauma triage and/or other prehospital care criteria have been met. They may also be used to review an individual's performance. Finally, the administrative data may be used by the billing department to complete the billing process.

Data Collected via PCR

There are many required components of a PCR (**TABLE 4-11**). Often, these requirements vary from jurisdiction to jurisdiction, mainly because different agencies obtain information from them. Although no universally accepted form exists, certain data points (uniform components of a PCR) are common in all areas. The benefits of collecting such information are significant, including the fact that national trends can be detected if all agencies collect and report the same information. For example,

TABLE 4-11 Sample Uniform Components of a PCR

Patient's name, sex, date of birth, and address
Dispatched as (When was the ambulance called? What was the nature of the call as reported by the dispatcher?)
Chief complaint
Location of the patient when first seen (including specific details, especially if the incident is a motor vehicle crash or when criminal activity is suspected)
Rescue and treatment given before your arrival
Signs and symptoms found during your patient assessment
Care and treatment given by you at the site and during transport
Response to treatment
Vital signs
SAMPLE history
Changes in vital signs and condition
Additional orders received from the hospital
Name of person receiving the patient report
Date of the call
Time of the call
Location of the call
Time of dispatch
Time of arrival at the scene
Time of leaving the scene
Time of arrival at the hospital
Patient's insurance information
Names and/or certification numbers of the AEMTs who responded to the call
Name of the transport destination
Type of response to the scene: emergency or routine

Abbreviations: AEMT, advanced emergency medical technician; PCR, patient care report; SAMPLE, Signs and symptoms, Allergies, Medications, Pertinent past history, Last oral intake, Events leading to the injury or illness

© Jones & Bartlett Learning.

approximately 10% of the nation's EMS calls involve pediatric and adolescent patients. Such information is invaluable and, when collected, forms uniform data points.¹² In addition, PCRs are used by

individual agencies to determine patterns of EMS responses. Busy times and high-call volume areas can be predicted to some extent by reviewing PCR data, and a thorough review of PCRs can set the stage for scheduling shifts and for system status management, including where units are placed.

Words of Wisdom

When you are quoting a patient, place quotation marks around the exact words stated. For example: Patient states his chest pain "feels like an elephant sitting on my chest."

Narrative Section

The narrative section of the PCR is arguably the most important portion of this report. Here you will describe all of the facts related to the EMS call. Be sure to include negative findings and important observations about the scene. Negative findings include those findings that warrant no medical care or intervention, but that, by seeking them, show evidence of the thoroughness of the AEMT's examination and history of the event. Do not record your conclusions or opinions about the incident. For example, you may write, "The patient admits to drinking today." This is a clear description that does not make any judgments about the patient's condition. You may also write that the patient's breath smelled of alcohol, but saying "The patient was drunk" is a judgment that may not be able to be supported. Choose your words carefully and thoughtfully. Ensure what you write is not an opinion, but is fact based on findings. Your job is to reproduce the important facts of the EMS call in writing.

Words of Wisdom

The time from the event until it goes to court may vary from very short to a couple of years. It is imperative that you document thoroughly because memories may become distorted after a long period of time.

When information is of a sensitive nature, note the source of the information. Be sure to spell words correctly, especially medical terms. If you do not know how to spell a particular word, then find out how to spell it, or use another word. Also

TABLE 4-12 Components of the Narrative Portion of a PCR

The following general information should be included for every call:

- Why you were called
- Scene size-up
- The patient's primary complaint
- Any secondary complaints
- Pertinent bystander or family information and the identity of the people who provide the information
- Pertinent history, medications, and allergies, or the lack thereof
- Position/location of the patient and your general impression of the patient on your arrival
- Any unusual circumstances of the call
- All assessment findings and pertinent negatives
- OPQRST-I for any complaint of pain
- MOI with any pertinent details
- At least two sets of vital signs, including breath sounds and glucose level
- Mental status
- Individual body system assessments
- Indications for any treatment given
- Description and time of treatment given
- Response, or lack of, to treatment given
- Any changes in the patient's condition
- Any treatment that should have been provided but was not and *why*
- Patient demographic information: age, sex, ethnic background
- Whether or not the patient was ambulatory, and how the person got to the stretcher/ambulance
- Patient's condition when turned over to other health care personnel

Additional information pertinent to the specific nature of the call should be included *in addition* to the information listed previously. For example, a PCR for a motor vehicle crash should include all of the information listed previously, as well as other findings, such as the following:

- Whether or not the patient was restrained
- Position of the patient in the vehicle
- Any ejection or death in the passenger compartment
- Location and extent of damage to the vehicle
- Whether or not the patient was ambulatory at the scene
- Approximate velocity of the crash, if known
- Any extrication or other delay
- Any loss of consciousness
- Any other pertinent details

Abbreviations: MOI, mechanism of injury; OPQRST-I, Onset, Provocation/palliation, Quality, Region/radiation, Severity, Timing, and any Interventions; PCR, patient care report

© Jones & Bartlett Learning.

be sure to record the time with all assessment findings. **TABLE 4-12** provides guidelines on points to be covered in the narrative portion of your report. Remember to follow any state reporting requirements.

Although the CHART and SOAP methods are widely used in health care, the chronologic method might better fit the EMS intervention.

Medical Terminology

Medical terms are mainly derived from Latin. Many new EMS providers are confused as to why they

need to learn this language: “If a person has a sour stomach, why can we not simply write ‘Patient complains of a sour stomach’ and be done with it?”

The reason to learn medical terms is to ensure accurate understanding by all people involved in the patient's care. What does “sour stomach” mean? Is there pain? Does the patient feel like they will vomit? Is the patient feeling as if they do not want to eat? There are many possible options. Through medical terminology, all readers—no matter where they are located in the chain of care—will understand the patient's complaint. Gastritis,

Words of Wisdom

Standardized Narrative Formats

Many EMS systems require the use of a standardized format to document care. Using one of these methods can ensure that important information is not omitted. Further, the standardized format allows others who consult your patient report, such as physicians, billing clerks, or administrators, to find information within it quickly. The two most common narrative formats used in health care are CHART and SOAP. The chronological format is commonly used as well.

CHART Method

CHART stands for Chief complaint, History and physical examination, Assessment, Treatment (Rx), and Transport. The strength of this method is that it breaks down the care and treatment into smaller, logical sections, making it easier to locate specific assessments or care without reading the entire report.

- C Chief complaint.** This section states the condition most urgently requiring EMS intervention. It is also a description of the scene, including where the patient was found (eg, Pt was restrained driver involved in head-on MVC).
- H History.** The history includes details relating to the current event and the patient's medical history prior to this event. Allergies, past medical history, current medications.
- A Assessments.** Describe all assessments you perform on the patient, including vital signs and the physical examination.
- R Treatments (Rx).** The *R* in CHART comes from the medical abbreviation for treatment. This section details all interventions that were performed.

- T Transport.** This final section explains how the patient was moved to the ambulance and possibly why the person was moved in that way; how the patient was transported (eg, how the person was positioned and secured); where the patient was taken, including the room number; and the person to whom the report was given and care was transferred (eg, nurse Jones).

SOAP Framework

The SOAP framework is another common method to structure documentation of the narrative.

- S Subjective.** This section includes information provided by the patient or others on the scene, such as the chief complaint. For example, the patient may complain of pain or nausea. You cannot measure how the patient is feeling and must rely on the patient's report.
- O Objective.** The objective section includes details you gather primarily through patient assessment. It includes information you can measure, such as vital signs, physical exam findings, and levels such as blood glucose or oxygen saturation.
- A Assessment.** Summarize key findings in the assessment section. If appropriate, provide your impression of what the patient's problem might be (eg, possible fractured lower leg, possible stroke).
- P Plan.** Within the plan area, document treatment provided for the patient.

Chronologic Order

This method allows you to explain the call in a story format from start (time of the initial dispatch) to finish (completion of the call).

an inflammation of the stomach, is understood equally in Ohio, Florida, England, and Thailand. Medical personnel around the globe speak the same language—Latin.

Medical terminology uses a system that combines prefixes, word roots, and suffixes to describe complaints or diseases. If a patient has a headache, then this can be described in medical terms as *cephalgia*. This term combines the Latin roots *ceph* (head) and *algia* (pain). When you are talking about medical issues with other health care providers, using appropriate medical language will help ensure accurate understanding. Taking a medical terminology course can certainly be helpful when working in medicine.

In Chapter 7, *The Human Body*, it is clear that Latin prevails. There may be slight spelling changes, but the meaning of the Latin roots, prefixes, and suffixes remains. These word parts, as well as common medical abbreviations and directional terms such as *superior* (toward the head), *lateral* (toward the side), and *distal* (away from a specific area), are discussed in Chapter 5, *Medical Terminology*.

Words of Wisdom

If you are unsure of an abbreviation, then always spell out the word completely.

Reporting Errors

Everyone makes mistakes. If you leave something out of a report or incorrectly record information, then do not try to cover it up. Rather, write down what did or did not happen and the steps that were taken to correct the situation. Falsifying information on the PCR is fraudulent and may result in suspension and/or revocation of your certification or license. More important, falsifying information may result in poor patient care, because other health care providers have the wrong impression of assessment findings or the treatment given. Document only the vital signs that were actually obtained. If you did not administer oxygen to the patient, then do not document that the patient was given oxygen.

What if the wrong drug or the wrong dose was given to a patient? What if the patient is accidentally dropped? Unfortunately, these things can and do happen. It is important that you document the event. Do not lie or cover it up. In your narrative, provide a factual account of what happened. For example, you might record the following information: “Medical control ordered one sublingual

nitroglycerin. Two sublingual nitroglycerin were given. Patient’s blood pressure was checked following administration and at subsequent intervals with no changes noted.” Or, “While loading the patient into the ambulance, the stretcher fell a total of 4 feet (1 m). Stretcher landed upright and the patient was not thrown from the stretcher. Patient was assessed and complained of being scared and having neck pain. Hospital advised.”

If you discover an error as you are writing your report, then draw a single horizontal line through the error, initial it, and write the correct information next to it (**FIGURE 4-15**). Do not try to erase or alter the error. This may be interpreted as an attempt to cover up a mistake.

If you discover you made an error after you submit your written report, then follow the same process of error correction by drawing a single line through the error, preferably in a different color ink, initial it, and date it. Ensure you add a note with the correct information. If you accidentally left out information, then begin a new section with the word “Addendum,” add the new information, and then

FIGURE 4-15 If you make a mistake in a handwritten report, then the proper way to correct it is to draw a single horizontal line through the error, initial it, and write the correct information next to it.

add the date and time and your initials. Know your own agency's policies regarding modification or addendums to medical records that you make after the fact.

If you discover you made an error after you submit an electronic report, most systems will allow for amendments but will prevent erasure in a completed document. Refer to the system's direction as to how to make an amendment to the original document. If there is no way to electronically change the report, the same procedure should be followed as for a written document. Simply follow the correction method used for a handwritten report on a printout of the electronic report.

Only the person who wrote the original report can revise it. Additions or notations added by others after the completion of the report may raise questions about the authenticity of the report and the confidentiality practices of your agency. Additions or notations by others can be submitted on a separate report.

Minimum Requirements and Billing

Billing and administration are significant reasons why PCR writing needs to be accurate and complete. Medicare and Medicaid payers will reimburse for ambulance transport only if the services are documented as being medically necessary. *Medically necessary* means it would have been unsafe or impossible to transport the patient by any other means. For complete and accurate revenue recovery, you must ensure all procedures performed are documented, insurance codes are obtained, and the appropriate **medical necessity** signature is secured (where required).

To ensure your service's billing information will result in payment from the responsible insurer, agency, or private payer, the PCR should indicate why a patient may have needed emergency care, especially in the case of private or scheduled transports. It is imperative that your documentation be accurate and complete so time is not spent correcting the documentation, thereby delaying the billing process. You will often be trained by your agency and its billing company about which additional forms you need to complete as a part of each EMS response. EMS providers must understand that completing billing paperwork and supplying the

TABLE 4-13 Significant Findings That Indicate Medical Necessity for Ambulance Transport

- Patient is transported in an emergency fashion (with lights and siren) and could not be transported safely by other means.
- Patient is unresponsive or in shock.
- Patient needs to be restrained to prevent injury to self or others.
- Patient requires emergency treatment while being transported (eg, oxygen therapy, IV therapy).
- Patient must be immobilized for transport or fracture management.
- Patient is experiencing signs and symptoms of an AMI or stroke.
- Patient is exhibiting signs and symptoms of acute respiratory distress or cardiac distress.
- Patient has experienced severe hemorrhage.
- Patient is bed-confined and able to be moved only by a stretcher due to condition.

Abbreviations: AMI, acute myocardial infarction; IV, intravenous

© Jones & Bartlett Learning.

most accurate and defensible information to the EMS agency are necessary portions of the call.

Medicare sets the standard for medical necessity. **TABLE 4-13** gives some of the significant findings that are required to show the patient needed to be transported by an ambulance rather than by other means.

Medical necessity also applies to the level of care provided for the patient. For example, it would be inappropriate to document that advanced life support interventions were provided to a patient who did not need them. It is therefore crucial to clearly document the patient's dispatch-reported condition, the actual patient condition the AEMT found on scene, EMS treatments and services rendered and the patient's response to those treatments, and an objective report of the patient's appearance and mental status.

Words of Wisdom

Document the use of any support services, such as helicopter or rescue services, and also the use of any mutual aid services in the PCR.

Signatures are another essential element to ensure your EMS agency is appropriately reimbursed for services provided. Every attempt should be made to obtain appropriate signatures from the patient or guardian.

Health Information Exchanges

Some EMS systems use a **health information exchange (HIE)** to improve sharing of data among EMS and other health care providers. HIEs allow EMS providers to access relevant health data (eg, past medical problems, medications, allergies, end-of-life desires), avoid unnecessary duplication of effort in data entry, and view patient outcomes related to hospital care. HIEs allow AEMTs to contribute to and access electronic health information on both a regular basis and during times of disaster, when accurate patient medical records may be destroyed or difficult to obtain.

Most HIEs follow the SAFR framework to improve patient care by giving health care providers rapid and universal access to accurate patient medical information.

- **Search.** EMS providers in the field can search for hospital and other records that will help them make treatment and transport decisions.
- **Alert.** Hospitals are notified of incoming EMS patients with automated systems that populate ED dashboards with information entered by EMS in the field.
- **File.** The data in EMS ePCRs are incorporated directly into patient's longitudinal health records.
- **Reconcile.** Feedback on outcomes and other hospital data are provided to EMS agencies for billing and quality improvement.

Documenting Refusal of Care

Refusal of care is a common source of litigation in EMS; therefore, thorough documentation is crucial. Competent adult patients have the right to refuse treatment and, in fact, must specifically provide permission for treatment to be initiated. If you are not able to persuade the patient to proceed with treatment, then document any assessment findings, emergency medical care given, your efforts to obtain

consent, and the patient's response to your efforts. Have the patient sign a refusal form (**FIGURE 4-16**). You should also have a family member, law enforcement officer, or bystander sign the form as a witness. If the patient refuses to sign the refusal form, then have a family member, law enforcement officer, or bystander sign the form verifying that the patient refused to sign. Depending on local protocols, you may be required to inform online medical control when a patient refuses care. For more on consent and refusal of care, see Chapter 3, *Medical, Legal, and Ethical Issues*.

Street Smarts

Contact medical control for direction if you are unsure of what to do with a patient who is refusing care. A physician may be able to offer a different perspective that convinces the patient to agree to treatment and/or transport. If the patient still refuses, then you must document that you tried everything possible to provide care for the patient.

Even if a patient refuses care, you must complete the PCR. If the patient refuses care or will not allow a complete assessment, then document that a proper assessment was not performed because of patient refusal. You will need to thoroughly document the advice you gave as to the risks associated with refusal of care. Report clinical information, such as the level of consciousness, showing the competency of the person refusing care. Note pertinent patient comments and any medical advice given to the patient by the physician or medical control through phone or radio. Include a description of the care that you wished to provide for the patient.

There are many local variations of requirements for patient refusals. **TABLE 4-14** provides a reasonable list of items that should be included within the PCR of a patient refusal. In many cases, the level of documentation necessary to demonstrate your assessment of patient competence to refuse and to record your efforts to adequately inform the patient of the risks of refusal and the patient's options will far exceed the degree of documentation that would have been necessary had the patient consented

TABLE 4-14 Components of a Thorough Patient Refusal Document

Complete assessment.

Evidence that the patient is able to make a rational, informed decision.

Documentation of complete assessment. If the patient refused care or did not allow a complete assessment, then document that the patient did not allow for proper assessment and document whatever assessments were completed.

Discussion with the patient as to which care/transportation the AEMT feels is in the best interest of the patient.

Discussion with the patient as to what may happen if the patient does not allow care or transportation. Typically, these consequences should be listed clearly and should include the possibility of severe illness/injury or death if care or transportation is refused.

Discussion with family/friend/bystanders to try to encourage the patient to allow care.

Discussion with medical direction according to local protocol.

Providing the patient with other alternatives: going to see a family doctor, having a family member drive the patient to the hospital.

Willingness of EMS to return if the patient changes their mind.

Signatures: Have a family member, law enforcement officer, or bystander sign the form as a witness. If the patient refuses to sign the refusal form, have a family member, law enforcement officer, or bystander sign the form verifying that the patient refused to sign.

Abbreviations: AEMT, advanced emergency medical technician; EMS, emergency medical services

© Jones & Bartlett Learning.

to transport to the hospital. As a rule, a refusal increases the importance and burden of the PCR relative to a transport situation.

Refusal of care concerns arise not only with patients who do not wish to be transported to the hospital, but also with those who refuse a certain aspect of care. For example, a victim of a motor vehicle crash may wish to be treated and transported but refuses to be fully immobilized. It is appropriate to carry out all other medical care and document the patient's refusal of spinal immobilization. Just because the patient refuses a cervical collar is no reason to deny oxygen. The same is true for the patient who wishes to use a local hospital

when the injuries dictate transport to a trauma facility. Anytime a patient refuses any part of the standard treatment, it needs to be documented in the PCR and the patient needs to sign for the care they are refusing.

Special Reporting Situations

In some situations, you may be required to file special reports with appropriate authorities. These may include incidents involving gunshot wounds, dog bites, certain infectious diseases, or suspected physical or sexual abuse. In case of suspected abuse, for example, you must document your objective findings and allow the legal system to investigate and make the ultimate determination of abuse or neglect. Other special situations include exposure or injury of the AEMT. If you treat and/or transport a coworker for an occupational exposure, then you should complete a full PCR along with the occupational exposure form. Learn your local requirements for reporting these incidents. Failure to report them may have legal

Words of Wisdom

Regardless of the method you choose for documentation, consistency is key. If you repeatedly use the same format, you are less likely to leave out pertinent information.

Patient Initiated Refusal of EMS

Patient Name: Doe, John

Inc Time Entered: 1824 hrs

I (or my guardian) have been informed regarding the state of my present physical condition to the extent I allowed an examination, and I (or my guardian) hereby refuse to accept such medical care and/or transportation as recommended by representatives of the EMS System above.

I (or my guardian) do hereby for myself, my heirs, executors, and administrators and assigns forever release and fully discharge said EMS system, its officers, employees, medical consultants, hospitals, borrowed servants or agents from any and all conceivable liability that might arise from this refusal of care and/or transportation, and I (and my guardian) therefore agree to hold them completely harmless. I (or my guardian) have been informed that a refusal of care and/or transportation for an evaluation may cause me to suffer PAIN, DISABILITY, LOSS of FUNCTION, WORSENING of my CONDITION, or even DEATH as a result of my illness/injury. As a competent adult, I (or my guardian) fully understand all of the above, and am/is capable of determining a rational decision on my own behalf.

Providers: When encountering a patient who is attempting to refuse EMS treatment or transport, assess their condition, and record whether the patient screening reveals any lack of medical decision-making capability (1-3,4a or b) or high risk criteria (5-8).

1) Medical Capacity: Was the patient disoriented to person? If yes, transport	☐ Yes ☒ No
2) Medical Capacity: Was the patient disoriented to place? If yes, transport	☐ Yes ☒ No
3) Medical Capacity: Was the patient disoriented to time? If yes, transport	☐ Yes ☒ No
4) Medical Capacity: Was the patient disoriented to situation? If yes, transport	☐ Yes ☒ No
5) Medical Capacity: Did the patient show altered level of consciousness? If yes, transport	☐ Yes ☒ No
6) Medical Capacity: Alcohol or drug ingestion by history or exam with slurred speech? If yes, transport	☐ Yes ☒ No
7) Medical Capacity: Alcohol or drug ingestion by history or exam with unsteady gait? If yes, transport	☐ Yes ☒ No
8) Medical Capacity: Patient does not understand the nature of illness and potential for bad outcome? If yes, transport	☐ Yes ☒ No
9) At Risk Criteria (Abnormal vital signs): For adults. Pulse greater than 120 or less than 60? If yes, consult	☐ Yes ☒ No
10) At Risk Criteria (Abnormal vital signs): For adults. Systolic BP less than 90? If yes, consult	☐ Yes ☒ No

Provide in the patient's own words why he/she refused the above care/service:

"Patient reports that despite the damage to his vehicle, he has only a small laceration on his finger and no other symptoms. He eventually agreed to allow EMS to evaluate him and provide a bandage for a small finger laceration (index finger, right hand). He agreed to follow-up with his primary care MD later today. When offered transport to the hospital he indicated, "No. thanks. I will be fine." Discussed plan with Dr Smith at St Elsewhere ED who agreed with plan and recommended reiterating to Mr Smith the importance of close follow-up with his primary care MD for tetanus prophylaxis and consideration of laceration care to include sutures.

FIGURE 4-16 (Continued)

consequences. It is important that the report be accurate and objective; it should be descriptive without making conclusions. It should be submitted in a timely manner and should include the names of all agencies, people, and facilities involved in the response.

You should also document the use of mutual aid services such as helicopters, specialized rescue teams, and other agencies called in to assist. Unusual occurrences should be documented as well, including having to secure the patient with restraining devices for safe transport or other unusual circumstances that arise.

Another special reporting situation is an MCI. The local MCI plan should have some means of recording important medical information temporarily (such as a triage tag that can be used later to complete the form). The standard for completing documentation in an MCI is not the same as for a typical call. In some areas, one trip report may be completed for the entire incident instead of individual reports for each patient.¹³ Your local protocols should have specific guidelines.

Submitting the Report

The PCR form itself and all the information on it are considered confidential documents, so ensure you are familiar with your state and local laws concerning confidentiality. All prehospital forms must be handled with care and stored in an appropriate manner once you have completed them. After you have completed a report, distribute the copies to the appropriate locations, according to state and local protocol. In most instances, a copy of the report will remain at the hospital and will become a part of the patient's record.

Depending on the requirements of the EMS system in which you work, you may not have the time to complete the full PCR while at the hospital. Even in these circumstances, however, a written record should be left with the patient. In these cases, most systems will have a “drop report” or “transfer report” (**FIGURE 4-17**). These single-page, abbreviated forms are used as a memory aid during an EMS call. If you are unable to remain at the hospital to complete the PCR, then copy these documents and leave them with the nurse or physician.

YOU are the Provider

Part 4

Medical control authorizes a patient refusal. Echoing back the authorization, you proceed to have the patient sign the appropriate forms. You emphasize that you would be happy to return, and advise her to call 9-1-1 again if she requires further treatment or transport.

YOU are the Provider SUMMARY**1. What are some nonverbal forms of communication you can use to perform an effective interview?**

The three main forms of nonverbal communication are eye contact, body language, and facial expression. When you are treating a patient, it is important that you understand and are aware of your own body language. Do not assume an aggressive posture. Make good eye contact, but do not stare. Speak calmly, confidently, and slowly. It is important for you to be attentive to facial expressions, body language, and eye contact—your own and your patient's. These

physical cues will help you and your patient to truly understand the message being sent.

2. As a general rule, how close should you be to the patient while you are interviewing?

Proxemics is the study of space and how the distance between people affects communication. The degree to which people feel comfortable depends on with whom they are communicating. As trust is established between two people, a smaller distance between the two people becomes comfortable. When you finally enter someone's intimate space, there

YOU are the Provider SUMMARY *continued*

must be a high sense of trust. On the basis of American culture, when you are interviewing a patient, you should use social distancing and remain between 4 and 10 feet (1 to 3 m) from the patient. In the context of active community transmission, providers should always attempt to maintain social distancing when not directly providing care and should wear appropriate personal protective equipment at all times.

3. What are two types of questions that are asked during a patient interview?

Open-ended and closed-ended questions are commonly used during a patient interview. Open-ended questions require a patient to provide some level of detail in an answer, whereas closed-ended questions can be answered in very short or single-word responses. Closed-ended questions are important to use when patients are unable to provide long or complete answers to questions. Open-ended questions allow a free flow of conversation; they let the patient direct you to what is bothering them.

4. Which techniques can be used to deescalate difficult situations?

To help defuse potentially escalating circumstances, stay calm. Talk to the patient openly and honestly. You will find that meeting hostility with calmness and confidence defuses a situation. Use open-ended questions, provide positive feedback, ensure the patient understands the questions, and continue to calmly ask questions. Consider the safety of the scene. If law enforcement officers are not present and a scene could escalate, then immediately request law enforcement backup. Ensure you have sufficient backup to provide safety for the patient, the crew, and yourself.

5. What is the main thing to remember when communicating with medical control?

It is important to plan and organize your radio communication before you push the transmit button. A concise, well-organized report demonstrates your competence and professionalism to all people who hear your report. Well-organized radio communications with the hospital will engender confidence in the receiving facility's physicians and nurses, as well as

others who are listening. In addition, the patient and family will be comforted by your organization and ability to communicate clearly. A well-delivered radio report puts you in control of the information, which is where you need to be.

6. Does this patient have the right to refuse transport to the hospital?

Competent adult patients have the right to refuse treatment and, in fact, must specifically provide permission for treatment to be provided by EMS or any other health care provider. Consult medical control as directed by local protocol. Also, ensure the patient is an adult or an emancipated minor; is able to make a rational, informed decision; and is not under the influence of alcohol or other drugs or the effects of an illness or injury. If a patient still refuses care after you have explained potential outcomes, then ensure they understand that you would be happy to return, and that they should not hesitate to call 9-1-1 again.

7. This patient refused care. Are you required to complete a PCR?

There are many local variations to document patient refusals, but generally, all patients that you come in contact with will require you to complete a PCR. Ensure you complete the PCR, including the patient assessment findings. If the patient refuses care or will not allow for a complete assessment, then document that a proper assessment was not performed because of patient refusal. You will need to document the advice you gave as to the risks associated with refusal of care. Report clinical information, such as the level of consciousness, showing the competency of the person refusing care. Note pertinent patient comments and any medical advice given to the patient by the physician or medical control through phone or radio. Include a description of the care that you wished to provide for the patient. Very often, the level of documentation necessary to support the assessment of patient competency to refuse and to record your efforts to explain the risks of refusal to the patient greatly exceeds the level of documentation necessary to care for and transport the patient to the hospital.

YOU are the Provider **SUMMARY** *continued***EMS Patient Care Report (PCR)**

Date: 6-5-20	Incident No.: 20108547	Nature of Call: Trauma	Location: 152 W Rollette Street		
Dispatched: 1623	En Route: 1626	At Scene: 1634	Transport: N/A	At Hospital: N/A	In Service: 1702

Patient Information

Age: 23
Sex: F
Weight (in kg [lb]): 149 kg (328 lb)

Allergies: None
Medications: None
Past Medical History: None
Chief Complaint: Laceration to right forearm

Vital Signs

Time: 1635	BP: Not obtained	Pulse: Not obtained	Respirations: 16	Spo₂: Not obtained
Time: 1642	BP: 112/84	Pulse: 74	Respirations: 16	Spo₂: 100% on room air
Time: 1644	BP: 112/80	Pulse: 71	Respirations: 14	Spo₂: 100% on room air

EMS Treatment (highlight all that apply)

Oxygen @_____ L/min via (circle one): NC NRM Bag-mask device		Assisted Ventilation	Airway Adjunct	CPR
Defibrillation	Bleeding Control	Bandaging	Splinting	Other:

Narrative

EMS dispatched to above location for woman with a laceration. On arrival, Greenville County Sheriff's Office (GCSO) law enforcement officers are present. Patient found seated on picnic bench in backyard. Patient states that her "drunk friend threw a broken bottle at me," subsequently breaking on her right forearm. Minor laceration approximately 1 inch in length, with no active bleeding. Bandage applied. Friends come out of house, appear intoxicated, aggressive, and belligerent. Request that law enforcement remove friends. Parties separated by officers. Remainder of physical exam is unremarkable. Patient offered transport to ED, which she refused. Per protocol, contacted online medical control, spoke with Dr. Helland, who granted refusal of services. AEMT explained the risks and consequences of refusing EMS to patient. The patient was asked to wash the injury with soap and water before bandaging. Advised that the patient should call EMS back if needed and seek further medical attention if any redness or swelling develops. Patient verbalized understanding and appeared competent to refuse. Documentation completed and refusal of treatment/transport form signed. Patient left in care of self and GCSO deputy on scene.

End of report

Prep Kit

Ready for Review

- Excellent communication skills are crucial in gathering and relaying pertinent information.
- AEMTs must have excellent person-to-person communication skills. You should be able to interact with the patient, family members, friends, bystanders, and other health care professionals.
- It is important for you to remember that people who are sick or injured may not understand what you are doing or saying. Therefore, your body language and attitude are very important in gaining the trust of both the patient and family.
- You may need to adjust your body language to account for different cultures. It is especially important to be aware of eye contact; direct eye contact is viewed as impolite or aggressive in some cultures.
- There are specific communication techniques you can learn to facilitate working with patients. You may opt to use open-ended questions in some instances and closed-ended questions in others. Other techniques include using the patient's proper name; speaking in a steady, calm tone; allowing the patient time to answer; listening to and acknowledging what the patient says; reassuring the patient; and protecting the patient's modesty. It is also important to tell the patient the truth, even if it is unpleasant.
- The presence of family, friends, and bystanders can be valuable or problematic. If someone is hindering your efforts to care for the patient, then ask the person to step outside for a moment, but remember to consider whether this will make the patient more anxious.
- Be careful what you say about the patient to others. Sharing patient information may be inappropriate and can be a Health Insurance Portability and Accountability Act violation.
- You must also take special care with people such as difficult patients, older adult patients, children, hard-of-hearing patients, visually impaired patients, non-English-speaking patients, and patients with other special needs.
- When you are working with difficult patients, use the same techniques, but make extra effort to be open and compassionate. Use open-ended questions, provide positive feedback, ensure the patient understands the questions, and continue to calmly ask questions. Consider the safety of the scene and request additional resources if needed.
- Verbal radio reports and in-person oral reports are crucial parts of transferring the patient's care; it is essential to report important information in a complete, precise way.
- Reporting and record-keeping duties are essential, but they should never come before the care of a patient.
- Radio and telephone communication links you and your team to other members of the EMS, fire, and law enforcement communities. You must know what your communications system can and cannot handle.
- The lines of communication are not always exclusive, so you should speak in a professional manner at all times.
- Components of an EMS communications system include a base station, from which a dispatcher communicates with field units. A repeater may be used; this special base station receives messages and signals on one frequency and then automatically retransmits them on a second frequency.
- In the ambulance, you will use both mobile and portable radios to communicate with the dispatcher and/or medical control. Cell phones and satellite phones are also commonly used.
- Digital radio may help clear up distorted or lost transmissions; digital trunked systems may carry simultaneous conversations on one physical channel.
- Telemetry is the capability of measuring vital life signs and transmitting these data to a

distant terminal—specifically, transmitting an electrocardiogram signal from the patient to a distant receiving station.

- At a large-scale incident, an interoperable communications system allows all agencies involved to share valuable information with each other in real time. This system utilizes a voice-over-Internet-protocol format to connect landlines, cell phones, and computers to create a seamless, reliable exchange of information.
- You will communicate with dispatch at many points during an emergency call. Communication begins when you are dispatched. You will also communicate with the dispatcher to report any special information en route, to confirm that you have arrived at the scene, and to request any additional needed resources.
- Once you are transporting the patient, you will communicate with the receiving facility to let it know what to expect. You must also report any significant changes in the patient's condition, especially if the patient seems worse. Medical control can then give new orders and prepare to receive the patient.
- You must also be able to communicate effectively by sending precise, accurate reports about the scene, the patient's condition, and the treatment that you provide.
- Along with your radio report and oral report, you must complete a formal written report about the patient before you leave the hospital. This is a vital part of providing emergency medical care and ensuring the continuity of patient care. This information guarantees the proper transfer of responsibility, complies with the requirements of health departments and law enforcement agencies, and fulfills your administrative needs.
- The PCR may be handwritten or electronic. Either way, it will include a checklist and a narrative portion. The report should be objective, accurate, and neat; this reflects good patient care and may be a valuable resource if a legal complaint is made.
- When you are talking about medical issues with other health care providers, use appropriate medical language to help ensure accurate understanding.
- If you make an error or omission in writing a report, then correct it and initial it. If you make an error in patient care, then write down what did or did not happen and the steps that were taken to correct the situation. Falsifying information on the PCR may result in suspension and/or revocation of your certification/license.
- Competent adult patients have the right to refuse treatment and, in fact, must specifically provide permission for treatment to be provided by EMS or any other health care provider. If they refuse care, then thorough documentation of that decision is crucial.

Vital Vocabulary

base station Any radio hardware containing a transmitter and receiver that is located in a fixed place.

cell phone A low-power portable radio that communicates through an interconnected series of repeater stations called cells.

channel An assigned frequency or frequencies that are used to carry voice and/or data communications.

closed-ended questions Questions that can be answered in short or single-word responses.

communication The transmission of information to another person—verbally or through body language.

computer-aided dispatch (CAD) Linked dispatch center computer consoles and vehicle-mounted mobile data terminals in which a computer collects and manages the call information and makes recommendations for which emergency medical services unit is closest based on existing dispatch policy.

cultural imposition When individuals impose their beliefs, values, and practices on

another because they believe their ideals are superior.

dedicated line A special telephone line that is used for specific point-to-point communications; also known as a hotline.

digital radio The transmission of information via radio waves using native digital (computer) data or analog (voice) signals that have been converted to a digital signal and compressed.

documentation The recorded portion of the AEMT's patient interaction, either written or electronic; it becomes part of the patient's permanent medical record.

duplex The ability to transmit and receive simultaneously.

emergency medical dispatcher (EMD) A specially trained member of the emergency medical services team who receives information, makes decisions about resource allocation, and relays that information in an organized manner during the emergency.

emotional intelligence The ability to understand and manage your own emotions and properly respond to others' emotions.

encoded A message that has been put into a code before it is transmitted.

enhanced 9-1-1 An emergency communications system that collects information about 9-1-1 calls from the telephone network, such as the telephone number and location of the caller, and displays this information on the dispatcher's computer terminal.

ethnocentrism A person's attitude that the person's own cultural values are more important than those of people from different cultures.

Federal Communications Commission (FCC) The federal agency that has jurisdiction over interstate and international telephone and telegraph services and satellite communications, all of which may involve EMS activity.

frequency The number of cycles (oscillations) per second of a radio signal.

health information exchange A system that allows EMS providers to access relevant health data (eg, past medical problems, medications,

allergies, end-of-life decisions), avoid unnecessary duplication of effort in data entry, and view patient outcomes related to hospital care.

interoperable communications system A communications system that uses a voice-over-Internet-protocol (VoIP) technology to allow multiple agencies to communicate and transmit data.

landline Communications system linked by wires, usually in reference to a conventional telephone system.

MED channels Very high-frequency and ultrahigh-frequency channels that the Federal Communications Commission has designated exclusively for EMS use.

medical necessity A standard used by Medicare to determine whether a patient's condition requires ambulance transport in a particular situation.

mobile data terminal (MDT) A small computer terminal inside an ambulance that directly receives data from the dispatch center.

mobile radio A radio that is mounted inside a vehicle and used to communicate with dispatch or medical control; it operates at lower power than a base station (20 to 50 watts) and is assigned to a specific radio frequency band.

multiplex Simultaneous transmission of multiple data streams, most often voice and electrocardiographic signals, in either or both directions over the same frequency.

noise Anything that dampens or obscures the true meaning of a message.

objective information Information that you observe and that is measurable, such as a patient's blood pressure.

open-ended questions Questions for which the patient must provide detail to give an answer.

paging The use of a radio signal and a voice or digital message that is transmitted to pagers ("beepers") or desktop monitor radios.

patient care report (PCR) The legal document used to record all patient care activities. This report has direct patient care functions as well as administrative and quality control functions. PCRs are also known as prehospital care reports.

portable radio A handheld two-way radio with a limited range and low power (1 to 5 watts).

prearrival instructions Instructions provided by the emergency medical dispatcher to an emergency caller to care for life-threatening emergencies until help arrives.

proxemics The study of space between people and its effects on communication.

rapport A trusting relationship that you build with your patient.

repeater A special radio station radio that receives messages and signals on one frequency and then automatically retransmits them on a second frequency.

scanner A radio receiver that searches or “scans” across several frequencies until the message is completed; the process is then repeated.

simplex Single-frequency radio; transmissions can occur in either direction but not simultaneously in both; when one party transmits, the other can only receive, and the party that is transmitting is unable to receive.

standing orders Written documents, signed by the EMS system’s medical director, that outline

specific directions, permissions, and sometimes prohibitions regarding patient care; also called protocols.

subjective information Information that is told to you but that cannot be seen, such as the symptoms a patient describes.

telemetry A process in which electronic signals are converted into coded, audible signals; these signals can then be transmitted by radio or telephone to a receiver with a decoder at the hospital.

therapeutic communication Verbal and nonverbal communication techniques that encourage patients to express their feelings and to achieve a positive relationship.

trunked radios Computerized sharing of radio frequencies by multiple units, agencies, or systems.

ultra high-frequency (UHF) band Radio frequencies between 300 and 3,000 MHz.

very high-frequency (VHF) band Radio frequencies between 30 and 300 MHz; the VHF spectrum is further divided into high and low bands.

Chapter 5

Medical Terminology

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Medical Terminology

Uses foundational anatomic and medical terms and abbreviations in written and oral communication with colleagues and other health care professionals.

KNOWLEDGE OBJECTIVES

1. Explain the purpose and the importance of being familiar with medical terminology. (p 180)
2. Explain the Greek and Latin origins of medical terms. (p 181)
3. Define medical eponyms, homonyms, antonyms, and synonyms; include examples for each. (pp 180–183)
4. Name the four word parts or components used to build medical terms; include examples of each. (pp 182–183)
5. Describe how compound words are created and how the plural is formed when using medical terminology; include examples of each. (pp 186–187)
6. Describe the anatomic position and why it is used. (p 187)
7. List the three planes of the human body. (p 188)
8. List medical terms associated with regional anatomy. (pp 189–190)
9. Explain the importance of using accurate medical terminology for direction, movement, and position in your documentation and other communication. (pp 191–194)
10. Describe the topography of the abdominal region, including the four abdominal quadrants and the nine abdominal regions. (p 195)
11. Identify specialized prefixes used to indicate position, direction, and location. (pp 195–196)
12. Define specific terms used to indicate the patient's position on the scene or prior to transport: prone, supine, Fowler position, and recovery (left lateral recumbent) position. (pp 195–197)
13. Interpret standardly accepted medical abbreviations, acronyms, and symbols. (pp 197–198)
14. Identify error-prone medical abbreviations, acronyms, and symbols. (pp 198–199)
15. Know appropriate terminology related to pharmacology. (pp 198–210)

SKILLS OBJECTIVES

There are no skills objectives for this chapter.

Introduction

As an advanced emergency medical technician (AEMT), it is imperative that you develop a strong working knowledge of medical terminology, the language of medicine and health care. Medical terminology is used to describe and record every aspect of patient care, including medical history, assessment results, treatment, and outcomes. The language of medicine is derived primarily from Greek and Latin terms. If you understand the origin of medical terms (words), the components (parts), and the guidelines for forming words, you will be able to identify and use medical terminology correctly and communicate effectively with other health care providers.

Consider what could happen if you, as an AEMT, used medical terminology incorrectly:

- A term used incorrectly in a radio report or documented improperly in the patient care report (PCR) could lead to the patient being given an ineffective or even harmful treatment at the hospital.
- The patient could lose trust in your ability to provide appropriate care.

Your comprehension of key terms, acronyms, symbols, and abbreviations is important for effective communication and documentation. Understanding medical terminology requires you to break down each word into its separate components—prefix, suffix, and root—and to have a good working knowledge of those parts. Learn the established and accepted medical terms and abbreviations for your local area. Some emergency medical services (EMS) systems have specific lists of approved medical abbreviations and terms you must use.

In addition to accepted terminology, you will undoubtedly hear some common slang terms used in EMS, such as “boarding a patient” for transport or “bagging” or “tubing” the patient during airway management. The more extensive your vocabulary is, the more competent you will seem to be by the rest of the medical community and the better the patient care you will be able to deliver. Download a medical terminology app or carry a field guide or documentation handbook, so you can quickly and easily look up any unfamiliar terms without memorizing page after page of terms (**FIGURE 5-1**).

FIGURE 5-1 Medical terminology apps are excellent resources to use to reference terms while working in the field.

© Jones & Bartlett Learning.

Words of Wisdom

Never use a medical term if you are uncertain of its meaning. If you cannot remember the word *femur*, then it is better to say thigh bone than to risk using an incorrect term.

Origins

Understanding the origins of medical terms helps you decipher the meanings of terms. Most medical terms have Greek or Latin origins. In general, medical terms that refer to disease are derived from Greek words. Words that refer to anatomic structures are usually derived from Latin words (**TABLE 5-1**). The original word and the meaning are often interesting. For example, the word *muscle* comes from a Latin word for mouse, because the movement of a muscle under the skin was thought to resemble the scampering of a mouse. The word *coccyx*, the lower end of the spine, originated from the Greek word for cuckoo because it resembles a cuckoo's bill.

Eponyms

The language used in medicine also comes from eponyms and terms that have resulted from advances in modern medicine, such as *fiberoptic* and

TABLE 5-1 Selected Medical Terms With Greek or Latin Origins

Greek	Medical Term	Latin	Anatomic Structure
burs/o	bursitis	dors/o, dors/i	back (dorsal)
cholecyst/o	cholecystitis	faci/o	face (facioplegic)
gloss/o	glossitis	lingua	tongue (linguistic)
hepat/ic	hepatitis	mamm/o	breast (mammogram)
nephr/o	nephritis	ren	kidney (renal)

© Jones & Bartlett Learning.

pacemaker. An **eponym** is the name of a disease, device, procedure, or drug that is based on the person who invented, discovered, or first described it. You use eponyms every day and may not even be aware of where they originated. For example, the diesel engine is named for its German inventor, Rudolf Diesel. The word *denim* is derived from the French *serge de Nîmes*, a serge fabric from the town of Nîmes in France. Medical eponyms sometimes appear in the possessive form (such as Hodgkin's disease) and sometimes not (Hodgkin disease). (Note: This text typically does not include the possessive form to align with the style of the American Medical Association.) As in this example, they often

include the name of the physician or surgeon who discovered, described, developed, identified, or invented a particular anatomic part or region, physiologic function or process, disease or syndrome, diagnostic or surgical procedure, treatment protocol, or instrument:

- McBurney point
- Foley catheter
- Babinski reflex
- Crohn disease
- Cesarean section
- Levine sign
- Apgar score

YOU are the Provider

Part 1

You and your partner are dispatched to a local elementary school to evaluate a child who has fallen. On arrival, you are directed to the playground, where a young boy is lying beneath a set of monkey bars on his left side, curled into a fetal position, sniffing and holding his abdomen. His first-grade teacher, Miss Jennings, tells you he fell from the top, approximately 6 feet (2 m), and has a lump on the right side of his head just above his eye. She says she's been trying to keep him still and has not let him try to get up.

Recording Time: 0 Minutes

Appearance	Awake
Level of consciousness	Alert
Airway	Open
Breathing	Adequate
Circulation	Appears normal

1. What is the correct medical term for the position in which the child is lying?
2. How can knowledge of medical terminology assist in your documentation of care for this patient?

In medical terminology, we can often use a single word to express a concept that might otherwise require many words of explanation. For example, you can say “arthritis” faster than you can say “painful inflammation of the joint.” In the next section, we will take a more in-depth look at commonly used medical terms and their meanings.

Homonyms

Incorrect pronunciation of medical terms can lead to misdiagnosis or other serious medical errors. Correct pronunciation and spelling are especially important with certain words known as **homonyms**—pairs of words that are pronounced almost the same way but are spelled differently and have different meanings. For instance, *ileum* (il'e-um) is the third portion of the small intestine, and *ilium* is the largest bone of the pelvis. Or compare *dysphagia* with *dysphasia*. These two words may be spelled similarly and sound almost identical, but they have very different meanings.

Safety

One type of medication error involves prescribing and dispensing “look alike, sound alike” (LASA) medications (eg, magnesium sulfate [MgSO₄] and morphine sulfate [MS or MSO₄]). The Joint Commission recommends focusing on prescription legibility through improved handwriting or the use of electronic prescriptions. Other solutions include physically separating LASA medications into different storage areas and using “tall man” or mixed-case lettering to emphasize the differences in drug names (eg, DOPamine versus DoBUTamine).

Words of Wisdom

A thorough knowledge of anatomy and an understanding of the context in which each term is typically used can help you determine (and spell) the correct word in a given situation. For example, the following terms are pronounced the same but have different spellings and meanings:

- *Ileum* is a part of the small intestine.
- *Ilium* is a bone forming the upper part of each half of the pelvis.

The word root *-phasia* means speaking, whereas *-phagia* means eating or swallowing. The prefix *dys-* means difficult or painful. *Dysphasia*, then, means difficulty speaking, while *dysphagia* means difficulty eating or swallowing.

Antonyms

Different word parts perform different functions. **Antonyms** are pairs of word roots, prefixes, or suffixes that have the opposite meaning of each other (**TABLE 5-2**).

Synonyms

Synonyms are pairs of word roots, prefixes, or suffixes that have the same or almost the same meaning. For example, the prefixes of the words *pneumonologist* and *pulmonologist* both mean lung, yet these words are not interchangeable. The reasons why are more historical than logical; the term *pneumonologist* simply has not gained acceptance, but the term *pulmonologist* has. **TABLE 5-3** shows more synonyms you are likely to encounter in your work.

TABLE 5-2 Selected Antonyms Used in Medical Terminology

Antonyms	Pairs of word roots, prefixes, or suffixes that have opposite meanings	Examples			
		Word part and meaning		Opposite word part and meaning	
		eu-	good	mal-	bad
		dextro-	right	sinistr/o	left
		ad-	toward	ab-	away from

TABLE 5-3 Selected Synonyms Used in Medical Terminology

Synonyms	Pairs of word roots, prefixes, or suffixes that have the same or almost the same meaning	Examples	
		Word part and meaning	Similar word part and meaning
		pulmon/o lung (as in pulmonologist)	pneum/o lung (as in pneumonia)
		mamm/o breast (as in mammogram)	mast/o breast (as in mastectomy)
		cardi/o heart (as in cardiology)	coron/o heart (as in coronary)
		nephr/o kidney (as in nephritis)	ren/o kidney (as in renal)
		angi/o vessel (as in angiogram)	vas/o vessel (as in vascular)

© Jones & Bartlett Learning.

Components of a Medical Term

When you encounter a new word, break it up into its component parts. Some medical terms are quite long, consisting of three or four parts. If you know the meaning of each part, then you can combine the definitions to determine the broader meaning of the word. Medical terms are composed of distinct parts that perform specific functions:

- **Prefix.** The portion that appears before the word root
- **Suffix.** The portion that appears after the word root
- **Word root.** The foundation of the term
- **Combining vowel.** Vowel that links one or more word roots to another component of a term

The way in which the parts of a word are combined determines its meaning. Changing or deleting any portion of a term can significantly alter its content. For example, *hyperglycemia* (hi'per-gli-se'me-ah) is too much blood glucose, and *hypoglycemia* (hi'po-gli-se'me-ah) is too little blood glucose. Thus, accurate spelling is essential in medical terminology.

Prefixes

Prefixes are often found in general language (for instance, *autopilot*, *submarine*, *tricycle*), and they are common in medical and scientific terminology. A prefix appears at the beginning of a word and

generally describes the location or intensity of the word root that follows. Of course, not all medical terms have prefixes. A prefix does not change the meaning of the word root—*cutaneous*, for example, means skin regardless of what precedes it. However, the prefix changes the meaning of the medical term as a whole by describing the what, how, why, or when of the root. To expand on our previous example, the prefix *sub-* means below; therefore, *subcutaneous* means “below the skin.” Another word, *atypical*, which means “not typical,” can easily be understood when you know it is formed from the prefix *a-*, which means not, and the word root *typical*.

By learning to recognize a few commonly used medical prefixes, you can determine the meaning of terms that may not be immediately familiar to you. *Hypo-*, for instance, is a prefix that means low. We can add it to the word root *volumen*, meaning “volume,” and the suffix *-emia*, meaning “blood,” to figure out what hypovolemia means:

Hypo + vol + emia = Low blood volume

Likewise, we can add *hypo-* to the word root *glyc/o*, meaning glucose, and the suffix *-emia*:

Hypo + glyc + emia = Low blood glucose

Sometimes, we have just two word parts to work with. In the following example, we can define “hypotension” by adding *hypo-* to the word root *tensio*, which means “to stretch”:

Hypo + tension = Low blood pressure

Master tables at the end of this chapter list medical terminology, including prefixes, suffixes, word roots, and abbreviations, you will use most every day in your work.

Numerical Prefixes

Many prefixes are used to indicate the number of sides, limbs, or sensory organs affected (“monocular vision,” for example). Other numerical prefixes are used to specify time, such as “octogenarian” (a person between 80 and 89 years of age) or to indicate quantities that are uncountable (semicomatose, for instance). Common numerical prefixes are listed in **TABLE 5-4**.

Suffixes

A *suffix* is a component added to the end of a word root. It changes or adds to the word’s meaning or provides further definition. In medical terminology, a suffix usually specifies a procedure, condition, disease, or part of speech. For example, the

suffix *-ase* indicates an enzyme. Lipase (*lip-*, which means fat, plus *-ase*) is an enzyme that digests fats. Gastritis, which means inflammation of the stomach, is a combination of the word root *gastr-*, which means stomach, and the suffix *-itis*, which means inflammation. Suffixes are able to change the medical term to a noun or adjective as needed.

Word Roots

The *word root* establishes the basic meaning of the word and frequently indicates a body part. Some books use the term *word root*; others use *root word*. The terms are synonymous. (Note: This textbook uses the term word root.) Prefixes are added to the beginning of a word root, and suffixes are added to the end of a word root. Changing the prefix or suffix will change the meaning of the term. Some word roots are complete words by themselves, but not all are. Furthermore, the same word root may have different meanings in different fields of study. You may have to consider the context of a word before assigning its meaning.

YOU are the Provider

Part 2

After briefly speaking with the teacher, you kneel down to get eye level with the child. “Hi, I’m an AEMT, and we’re here to take care of you. My partner, Matt, is going to hold your head really still while we talk for a minute. Does your head or your tummy hurt?”

He says his name is Kevin and his stomach hurts more than his head does. He is alert and oriented to person, place, time, and event. His respiratory rate is 22 breaths/min and normal, and his radial pulse is strong and regular, with a rate of 104 beats/min. He says he has felt dizzy all morning, and it made him fall. Miss Jennings tells you Kevin has type 1 diabetes. The school nurse has arrived and indicates that his mother reported his glucose level was 183 mg/dL when he arrived at school this morning. The nurse also states he is not allergic to any medications and that she normally checks his glucose level just before lunch each day.

Recording Time: 3 Minutes

Respirations	22 breaths/min
Pulse	104 beats/min
Skin	Cool and dry
Oxygen saturation (SpO₂)	98%
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

- Why would you want to avoid using medical terminology when talking to this patient?
- What are the correct medical terms to describe Kevin’s mental status and blood glucose level?
- How would you document that the patient has no medication allergies?

TABLE 5-4 Common Numerical Prefixes

Prefix	Meaning	Example	Definition
un-	One	unilateral	Affecting one side of the body
dipl-	double or in pairs	diplopia	Double vision
null-	none	nullipara	A woman who has never given birth
primi-	first	primigravida	A woman pregnant for the first time
multi-	many	multipara	A woman who has given birth to more than one child
bi-	two	bilateral	Pertaining to both sides of the body
tri-	three	trigeminy	Irregular heart rhythm consisting of two normal beats followed by one premature beat
quad-	four	quadriplegia	Paralysis of all four extremities
tetra-	four	tetralogy of Fallot	A congenital anomaly involving four anatomic abnormalities of the heart
quint-	five	quintipara	A woman who has had five pregnancies resulting in five live births
sexti-	six	sextuplets	Six offspring of the same pregnancy
septi-	seven	septuplets	Seven offspring of the same pregnancy
octo- or octi-	eight	octigravida	A woman pregnant for the eighth time
nona-	nine	nonan	Occurring on the ninth day
deca-	ten	decagram	Measurement of 10 grams
semi-	half; part	semipermeable	Partially permeable
hemi-	half; one sided	hemiplegia	Weakness on one side of the body
ambi-	both	ambidextrous	Able to use right and left hands equally
pan-	all, entire	pandemic	An epidemic over a wide area

© Jones & Bartlett Learning.

Colors

Several word roots are used to describe color. The most common include those listed in **TABLE 5-5**.

Combining Forms and Vowels

Some word roots, prefixes, and suffixes cannot combine with other word forms without help (**TABLE 5-6**). To make pronunciation easier, sometimes it is necessary to change the last letter or the last few letters of a word root or prefix when a suffix is added. These letters, called combining vowels, facilitate the formation of new, more complex terms. They often consist of a vowel, most

commonly *o*, added to a word root to create a combining form. A **combining form** is a word root, prefix, or suffix with an added vowel, known as a *combining vowel*. For example, in *osteopathic*, the first word root is *osteon* (Greek for bone). The *n* is dropped and the combining vowel *o* is added to create the combining form *oste/o*. Thus, adding the *o* facilitates the addition of a second combining form, *-pathy* (from the word root *patho-*, meaning disease).

Let's take another example. The word root *gastr-*, which means stomach, cannot combine gracefully with *megaly*, which means enlargement. The resulting term "gastrmegaly" would be awkward to

TABLE 5-5 Word Roots That Describe Color

Root	Meaning	Example	Definition
cyan/o	blue	cyanosis	Blue discoloration of the skin
leuk/o	white	leukocyte	White blood cell that fights infection
erythr/o	red	erythrocyte	Red blood cell that contains hemoglobin to carry oxygen
cirr/o	yellow-orange	cirrhosis	Inflammation of an organ, such as cirrhosis of the liver, which causes yellow-orange pigmentation of the skin
melan/o	black	melenia	Black, tarry stool caused by upper GI bleeding
poli/o	gray	poliomyelitis	An acute viral disease that attacks the gray matter of the brain
alb-	white	albinism	A condition in which a person's skin, hair, and eyes lack pigmentation (white hair, very pale skin, and a nonpigmented iris)
chlor/o	green	chlorophyll	A green pigment in leaves that is necessary for the plant to carry out photosynthesis

Abbreviation: GI, gastrointestinal
© Jones & Bartlett Learning.

TABLE 5-6 Selected Combining Forms

Combining Form	Meaning	Combining Form	Meaning
brachi/o	arm	pil/o	hair
cardi/o	heart	steth/o	chest
carp/o	wrist	thorac/o	chest, thorax
cephal/o	head	thyr/o	thyroid gland
cervic/o	neck	trache/o	trachea
encephal/o	brain	ureter/o	ureter
faci/o	face	vas/o	vessel
gloss/o	tongue	vesic/o	bladder, blister
nas/o	nose	viscer/o	viscera
ot/o	ear		

© Jones & Bartlett Learning.

pronounce and would have an odd spelling. A hyphen at the end of a word root indicates that *gastr-* is not a complete word. Adding a vowel to it, in this case an *o*, solves the problem. The result, *gastr/o*, is referred to as a combining form because it is used

when combining the root with other roots or suffixes. *Gastr/o + megaly* makes *gastromegaly*, or enlargement of the stomach. If the suffix begins with a vowel, then a combining vowel is unnecessary. For example, *gastr- + -ic = gastric*. No additional letters are needed to form the word.

When adding combining vowels to word roots, use the following guidelines:

- Use a combining vowel before a suffix that begins with a consonant (eg, *cyt/o + logy*).
- Use a combining vowel to join other word roots (eg, *gastr/o/enteritis*).
- Do not use a combining vowel before a suffix that begins with a vowel (eg, *gastritis*, not *gastroitis*).

Some other examples of combining forms and vowels are:

- *cardi/o + logy* = cardiology (study of the heart)
- *neur/o + logy* = neurology (study of the nervous system)

Compound Words

Some medical terms contain more than a one-word root. This type of word is called a **compound word**. In compound words, each word root retains its basic meaning. Simple examples of compound words containing two word roots are *electrocardiogram*

and *thermometer*. A more complicated example is *osteoarthritis*. The combining form *osteo* comes from the word root *ost-*, meaning bone. The word root *arthr-* means joint or joints. The suffix *-itis* means inflammation. Therefore, the combined word *osteoarthritis* means inflammation of the bone joints.

Plural Endings

To change a medical term from singular to plural, certain rules apply. In most cases, as with other words in English, the plural is formed simply by adding an *-s* to the singular word. *Lung* becomes *lungs*, for instance. However, for some medical terms, forming the plural is more complicated:

- Singular words ending in *-a* change to *-ae* in the plural.
 - Example: *vertebra* becomes *vertebrae*
- Singular words ending in *-is* change to *-es* in the plural.
 - Example: *diagnosis* becomes *diagnoses*
- Singular words ending in *-ex* or *-ix* change to *-ices*.
 - Example: *apex* becomes *apices*
- Singular words ending in *-on* or *-um* change to *-a*.
 - Examples: *ganglion* becomes *ganglia*; *ovum* becomes *ova*
- Singular words ending in *-us* change to *-i*.
 - Example: *bronchus* becomes *bronchi*

Topographic Anatomy

The surface of the body has many superficial visible features that serve as guides or landmarks indicating the structures that lie beneath them. Taken together, these features make up the body's topography (from the Greek word *topos*, meaning place, and *-graphy*, meaning description). Familiarize yourself with these living landmarks—the **topographic anatomy** of the body—to perform a thorough assessment.

To describe topography accurately, you must imagine the body in a fixed position, known as the **anatomic position**: the person is standing, facing you, arms at the sides, with the palms of the hands facing forward, so the thumbs point away from the body. This position serves as a shared reference

point, so the meaning of various directional terms stays constant, regardless of body position or movement. For example, a person reports pain in his arm and you need to document it. Whose left or right do you use? To be consistent, the reference point health care providers should use is the patient's left and right in the anatomic position.

Words of Wisdom

There is only one anatomic position. Don't confuse this concept with the patient's position—prone or supine, for instance—or with patient positioning, such as the Fowler or Trendelenburg position.

Anatomic Planes and Axes of the Body

An anatomic plane of the body is an imaginary flat surface—imagine sheets of glass slicing through the body, dividing it horizontally and vertically into sections (**FIGURE 5-2**). An *axis* is an imaginary line that divides the body equally and creates

FIGURE 5-2 Planes and axes of the body.

© Jones & Bartlett Learning.

a point of rotation. Think of a skewer or pole through the middle of an object. The body can be divided along three main axes, to create the following planes:

1. **Coronal plane.** Imagine a sheet of glass (the plane) slicing the body vertically, from ear to ear, dividing it into front (ventral) and back (dorsal) portions. We call this the frontal or **coronal plane**—easy to remember, because “corona” means head.
2. **Transverse (axial) plane.** Now imagine a plane passing horizontally through the body at the waist, creating top and bottom portions. This slice is referred to as the **transverse (axial) plane**.
3. **Sagittal (lateral) plane.** Finally, we divide the body vertically again, but this time slicing it from front to back. This is the **sagittal (lateral) plane**. *Sagitta*, Latin for arrow, describes the way in which the straight line of this plane divides the body into two sides. A sagittal plane might not go through the midline of the body. If it does, then it is called the **midsagittal plane (midline)**, which divides the body into equal left and right halves. Your nose and navel are found along this imaginary line. Other sagittal planes lie parallel to the midline.

TABLE 5-7 Anatomic Planes of the Body

Plane of the Body	Description
Coronal	Front and back
Transverse	Top and bottom
Sagittal • Midsagittal (midline)	Left and right (divides the body at any point on or parallel to the midline) • Left and right (divides the body into equal left and right halves)

© Jones & Bartlett Learning.

The three axes along which the body can be divided are as follows, and are also shown in Figure 5-2:

1. The **anteroposterior axis** runs perpendicular to the coronal plane.
2. The **longitudinal axis** runs perpendicular to the transverse plane.
3. The **horizontal axis**, also called the medio-lateral axis, runs perpendicular to the sagittal plane.

These planes help you to identify the location of internal structures and understand the relationships between and among the organs (**TABLE 5-7**).

YOU are the Provider

Part 3

You explain to Kevin that your partner is going to hold his head still and you are going to roll him over onto his back so you can check where it hurts. He presents with a golf ball-size hematoma and a small laceration just above his right eye. There is no active bleeding, and his pupils are equal and reactive. His abdomen is very tender on the right side just below his ribs, and you note bruising in the area. He denies pain in any other area. He tells you he took his insulin this morning and ate breakfast before school.

Recording Time: 8 Minutes

Respirations	22 breaths/min
Pulse	108 beats/min
Skin	Cool and dry
Oxygen saturation (SpO ₂)	99%
Pupils	PERRLA

6. Describe the position of the patient's head injury.
7. What is the abbreviation for the abdominal quadrant that is tender to the touch?

A **cross section** is obtained by slicing across an object, perpendicular to its long axis, as you would do if you wanted to count the rings in a tree trunk. A **longitudinal section**, in contrast, is a view of an object cut along its long axis. In medicine, this slicing, of course, is often imaginary, or can be accomplished with, say, a camera or a beam of radiation, rather than a scalpel.

Specific Areas of the Body

In addition to using planes and topographic landmarks, many body areas have specific names. When

a person is injured, AEMTs rely on anatomic planes, body surfaces, and imaginary lines to describe the location of the injury. Familiarizing yourself with these body regions will not only help you communicate with other professionals, it will also help you break down other terms, because many of them are used as word roots. For example, “sternocleidomastoid” is a combination of *sterno-*, *cleido-*, and *-mastoid*, which refer to the sternum, clavicle, and mastoid process, respectively. If you understand those roots, then you will be able to locate the origin and insertion of this large neck muscle. The most common body regions are described in **TABLE 5-8**.

TABLE 5-8 Terminology Associated With Specific Body Regions

Term	Word Parts	Definition
Abdominal	abdomin/o = abdomen -al = pertaining to	Pertaining to the abdomen
Axillary	axill- = armpit -ary = pertaining to	Pertaining to the armpit
Brachial	brachi/o = arm between the shoulder and elbow -al = pertaining to	Pertaining to the upper arm
Buccal	bucc/o = cheek -al = pertaining to	Pertaining to the cheek
Cardiac	cardi/o = heart -ac = pertaining to	Pertaining to the heart
Cervical	cervic/o = neck -al = pertaining to	Pertaining to the neck
Cranial	crani/o = cranium or skull -al = pertaining to	Pertaining to the skull or cranium
Cutaneous	cutane/o = skin -ous = pertaining to	Pertaining to the skin
Deltoid	N/A – word root	Pertaining to the shoulder muscle
Femoral	femor/o = femur -al = pertaining to	Pertaining to the thigh
Gastric	gastr/o = stomach -ic = pertaining to	Pertaining to the stomach
Gluteal	glute/o = buttocks -al = pertaining to	Pertaining to the buttocks
Hepatic	hepat/o = liver -ic = pertaining to	Pertaining to the liver

(continues)

TABLE 5-8 Terminology Associated With Specific Body Regions (*continued*)

Term	Word Parts	Definition
Inguinal	inguin- = groin -al = pertaining to	Pertaining to the groin (depressions in the abdominal wall near the thighs)
Lumbar	lumb/o = loin -ar = pertaining to	Pertaining to the loin (the lower back between the ribs and pelvis)
Mammary	mamm/o = breast -ary = pertaining to	Pertaining to the breast
Nasal	nas/o = nose -al = pertaining to	Pertaining to the nose
Occipital	occiput = the back of the head or skull -al = pertaining to	Pertaining to the inferior posterior region of the head
Orbital	orbit = the bones surrounding the eye -al = pertaining to	Pertaining to the bones surrounding the eye
Pectoral	pector- = breast or chest -al = pertaining to	Pertaining to the chest
Plantar	plant/o = sole of the foot -ar = pertaining to	Pertaining to the sole of the foot
Popliteal	poplit- = posterior knee -al = pertaining to	Pertaining to the posterior knee
Pulmonary	pulm/o, pulmon/o = lungs -ary = pertaining to	Pertaining to the lungs
Renal	ren/o = kidney -al = pertaining to	Pertaining to the kidneys
Sacral	sacr/o = the lowest portion of the spine -al = pertaining to	Pertaining to the lowest portion of the spine
Temporal	temp/o, tempor/o = temples -al = pertaining to	Pertaining to the temples of the head
Umbilical	umbilic- = navel -al = pertaining to	Pertaining to the navel
Volar	vol- = palm of hand or sole of foot -ar = pertaining to	Pertaining to the sole of the foot or palm of the hand

© Jones & Bartlett Learning.

Body Cavities

The human body contains several cavities, each containing various organs and other structures. These cavities can be grouped into dorsal cavities, which are more posterior, and ventral cavities, which are anterior. The dorsal cavities include the cranial cavity, which contains the brain, and the spinal cavity, which surrounds the spinal cord. The ventral

cavities include the thoracic cavity, which encloses the heart, lungs, and great vessels; the abdominal cavity, which holds several digestive and endocrine organs; and the pelvic cavity, which contains many digestive organs as well as the female reproductive organs. The abdominal and pelvic cavities can be referred to together as the abdominopelvic cavity (**FIGURE 5-3**). Another cavity is the retroperitoneal cavity, which is separate from and lies posterior

(dorsal) to the abdominal cavity and contains different organs, most notably the kidneys.

Directional Terms

Directional terms used in the study of anatomy describe relative positions of body parts as well as imaginary anatomic divisions. When you discuss, describe, or document the location of pain or injury, use the correct directional terms (**FIGURE 5-4**). **TABLE 5-9** provides the basic terms

FIGURE 5-3 Body cavities.

© Jones & Bartlett Learning.

FIGURE 5-4 Directional terms indicate distance and direction from the midline.

© Jones & Bartlett Learning.

TABLE 5-9 Common Directional Terms

Common Term	Directional Term	Definition
Right and left	Right Left	The patient's right The patient's left
Top and bottom	Superior Inferior	Closest to the head Closest to the feet
Middle and side	Medial Lateral	Closest to the midline Farthest from the midline
Closest and farthest	Proximal Distal	Closest to the point of attachment Farthest from the point of attachment
In and out	Superficial Deep	Closest to the surface of the skin Farther inside the body
Front and back	Anterior (ventral) Posterior (dorsal)	The front of the body The back of the body

© Jones & Bartlett Learning.

used in medicine. Because every direction has an opposite—above and below, front and behind, etc—directional terms in medicine tend to occur in pairs.

Superior and Inferior

The **superior** portion of any body part is the portion above or closest to the head from a specific reference point. The body part closest to the feet is the **inferior** portion. These terms are used to describe the relationship of one structure to another. For example, the knee is superior to the foot and inferior to the pelvis.

Lateral and Medial

Parts of the body that lie farther from the midline are described as **lateral** (outer). The parts that lie closer to the midline are described as **medial** (inner). For example, the knee has medial (inner) and lateral (outer) aspects (surfaces).

Proximal and Distal

It is sometimes useful to describe a portion of an extremity relative to its distance from the midline of the body. **Proximal** describes structures that are closer to the body. For example, a fracture of the proximal humerus would involve the end of the bone that is closest to the shoulder. **Distal** indicates structures that are farther from the trunk—that is, nearer to the free end of the extremity. Using our previous example, a fracture of the distal humerus is one that involves the end of the bone farther from the body (adjacent to the elbow). You can use these terms to describe the relationship of one structure to another. For example, the elbow is distal to the shoulder and proximal to the wrist and hand.

Superficial and Deep

Superficial means closer to or on the surface of the skin. **Deep** means farther inside the body and away from the skin.

YOU are the Provider

Part 4

“Well, Kevin, we need to take you to the hospital so they can check that bump on your head and find out why your tummy hurts. Matt and I are going to put you on a board with some seat belts and fix it so your head doesn’t move. Don’t worry, it won’t hurt, and we will be right here with you. Miss Jennings called your mom and dad, and they’re going to meet us at the hospital.”

After applying a cervical collar and securing the patient on a backboard with straps and a cervical immobilization device, the child is loaded onto the stretcher and into the ambulance. His heart rate is regular and 98 beats/min. His blood pressure is 96/54 mm Hg and respirations are 18 breaths/min and normal, but his skin is a little cool and clammy to touch. He has good, equal breath sounds. His oxygen saturation (SpO₂) is 96%. You apply a small bandage to his forehead and reassess his abdomen. You note that it is still very tender to the touch and appears a little more discolored than it was initially.

Recording Time: 13 Minutes

Respirations	18 breaths/min, normal
Pulse	98 beats/min
Skin	Cool, clammy
Blood pressure	96/54 mm Hg
Oxygen saturation (SpO₂)	96%
Pupils	PERRLA

8. Why is knowledge of anatomy pertinent when assessing and treating this patient?
9. What is the medical term for clammy skin?
10. What is the medical term for a phenomenon (such as pain, swelling, or a rash) affecting both sides of the body?

Anterior and Posterior

Anterior refers to the belly side of the body. Another term for anterior is **ventral**. **Posterior** refers to the spinal side of the body, including the back of the hand (recall, the palms face forward when the body is in the anatomic position). Another term for posterior is **dorsal**. In human medicine, the terms anterior and posterior are used more frequently than the terms ventral and dorsal, which are more common in the veterinary and zoologic sciences.

Palmar and Plantar

The front region of the hand is referred to as the palm or **palmar** or volar surface. The bottom of the foot is referred to as the **plantar** or volar surface.

Apex

The **apex** (the plural is *apices* or *apexes*) is the tip of a structure. For example, the apex of the heart is the bottom (inferior portion) of the ventricles in the left side of the chest.

Movement and Positional Terms

All body movement, from the simplest grasp to the most graceful ballet step, can be broken down into a series of simple components and described with specific terms. As with the terms describing anatomic location and direction, an accepted set of terms describes body movement. These are particularly useful in explaining mechanism of injury.

Range of motion is the full distance that a joint can be moved. In the anatomic position, moving the distal point of an extremity toward the trunk is usually called **flexion**. For example, flexion of the elbow brings the hand closer to the shoulder, flexion of the knee brings the foot up to the buttocks, and flexion of the fingers forms the hand into a fist.

In certain cases, specific terms are used to clarify movement, such as in the foot. Dorsiflexion is movement of the foot toward the dorsal aspect, and plantar flexion describes movement toward the sole. **Extension** is the return of a body part from a flexed position to the anatomic position. In the anatomic position, all extremities are in extension. **Abduction** of an extremity moves it away from the midline. **Adduction** moves the extremity toward the

FIGURE 5-5 **A.** Elbow flexion and extension. **B.** Shoulder abduction and adduction.

© Jones & Bartlett Learning.

midline (**FIGURE 5-5**). A patient's neck can be in one of several positions when the patient is lying supine (**FIGURE 5-6**).

The prefix *hyper-* is often added to the terms *flexion* or *extension* to indicate a mechanism of injury. Hyper- indicates excess, for example, when a joint moves beyond its physiologic range of motion, possibly resulting in injury. The term **hyperflexion** refers to a body part that was flexed beyond its normal range of motion. **Hyperextension** refers to extension of a body part beyond its normal range of motion. An example of a hyperextension injury is one that occurs when a person falls on an outstretched hand, resulting in a distal radius fracture. A hyperflexion injury of the back can occur while bending. Wrist injuries can also be described using the terms **supination** and **pronation**. Turning the palms upward (toward the sky) constitutes supination of the forearm. Turning the palms downward (toward the ground) pronates the forearm.

Internal rotation means turning the anterior portion of an extremity toward the midline. The lower extremity is internally rotated when the

**A****B****C**

FIGURE 5-6 Positions of the neck in a patient found in a supine position. **A.** Neutral. **B.** Flexed. **C.** Extended.

© Jones & Bartlett Learning.

toes are turned inward. **External rotation** means turning an extremity away from the midline. Often, when you are comparing an injured extremity with the uninjured extremity, you will note rotational deformities. A hip can be dislocated anteriorly or posteriorly. In an anterior hip dislocation, the foot is externally rotated and the head of the femur is palpable in the inguinal area (the lower lateral regions of the abdomen and the groin). In the more common posterior hip dislocation, the knee and foot are usually flexed and internally rotated. The term *rotation* can also be applied to the spine. The spine is rotated when it twists on its axis. Placing the chin on the shoulder rotates the cervical spine.

Words of Wisdom

Use the correct anatomic terminology in your PCR. It makes the report more useful to hospital personnel and enhances your professional image as an AEMT.

Other Directional Terms

A body part or condition that appears on both sides of the midline is said to be **bilateral**. For example, the eyes, ears, hands, and feet are bilateral structures. This is also true of structures inside the body, such as the lungs and kidneys. Structures that appear on only one side of the body are said to be **unilateral**. For example, the spleen is only on the left side of the body, and the liver is predominantly on the right side. The terms *unilateral* and *bilateral* can also describe the location of pain, numbness, itching, or other phenomena; for example, pain on only one side of the body is unilateral pain. You may also use the terms *ipsilateral* and *contralateral*. The term **ipsilateral** refers to the same side of the body. A patient having a stroke in the right hemisphere of the brain will usually have facial drooping ipsilaterally, in this case on the right side. **Contralateral** refers to the opposite side of the body. The same patient would have hemiplegia on the contralateral, or the opposite, side from the area of brain injury.

FIGURE 5-7 The abdomen is divided into four quadrants. RUQ indicates right upper quadrant; LUQ, left upper quadrant; RLQ, right lower quadrant; and LLQ, left lower quadrant.

© Jones & Bartlett Learning.

As part of your assessment process, you will palpate the abdomen and report your findings. Therefore, you must be able to describe the exact location of areas of the abdomen. The abdominal cavity is divided into four equal parts called **quadrants**: the right upper quadrant (RUQ), left upper quadrant (LUQ), right lower quadrant (RLQ), and left lower quadrant (LLQ). The quadrants are formed from two lines intersecting at the umbilicus (**FIGURE 5-7**). Pain or injury in a given quadrant usually arises from or involves the organs that lie in that quadrant. Again, remember right and left refer to the patient's right and left, not yours.

To describe location even more specifically, the abdomen can also be divided into nine regions (**FIGURE 5-8**).

FIGURE 5-8 Abdominal regions.

© Jones & Bartlett Learning.

Prefixes Indicating Position, Direction, and Location

Specialized prefixes are used to specify position, direction, or location. Such terms describe movement of the body or something within it, such as a blood clot or tumor metastasis. These prefixes indicate the location of an organ, foreign body, or mass; describe a surgical procedure and the medical instrument used to perform it; or refer to the direction of radiation or ultrasound waves used in diagnosis or treatment. Of course, these are just a few examples of how these versatile prefixes are used in medicine. Which words come to mind as you study **TABLE 5-10**?

Position of the Patient

You will use specific terms to describe the patient's position as you find the person on the scene or

TABLE 5-10 Prefixes Specifying Position, Direction, or Location

Prefix	Meaning	Example	Description
To/From			
ab-	away from	abduction	Away from the midline of the body, or a specified point of reference
ad-	to, toward	adduction	Toward the midline of the body
Above/Below/Around			
circum-	around, about	circumferential burn	A burn around an entire area (arm, chest, abdomen, etc)
de-	down from, away	decay	To waste away
contra-	against, opposite	contraindicated	Something that is not indicated
epi-	above, upon, on	epigastric	Above or over the stomach
infra-	below, under	infrathoracic	Below or at the bottom of the thorax
para-	near, beside, beyond, apart from	parasternal	Near the sternum
peri-	around	pericardium	The sac around the heart
retro-	behind	retroperitoneal	The area behind the peritoneum
sub-	under, below	subcutaneous	Under the skin
supra-	above, upper	suprasternal notch	Top of the sternum
trans-	across, through, beyond	transvaginal	Across or through the vagina
Outside/Inside			
ecto-	out, outside	ectopic pregnancy	Pregnancy where the embryo develops outside of the uterus
endo-	within	endoscopy	View inside the body (with an endoscope)
extra-	outside, in addition	extraneous	Existing or belonging outside the organism
intra-	inside, within	intrauterine	Within the uterus
ipsi-	same	ipsilateral	On or affecting the same side
Within			
inter-	between	intercostal	Between the ribs

when you are ready to transport the patient to the emergency department (**FIGURE 5-9**).

Prone and Supine

The body is in the **prone** position when lying face-down; it is **supine** when lying faceup.

Fowler Position

The **Fowler position** was named after an American surgeon, George R. Fowler, at the end of the nineteenth century. Dr. Fowler placed his patients in a sitting position with their heads elevated to a 90° angle

to help them breathe easier and to control their airways. A patient who is sitting straight up, with the knees either bent or straight, is described as being in the Fowler position. Patients in the semi-Fowler position are sitting with their back at a 45° angle. This position is generally a position of comfort for those who do not need spinal motion restriction.

Recovery Position

The recovery position helps maintain a clear airway in an unresponsive patient. In this position, the patient is lying on the left side, with the head resting

© Jones & Bartlett Learning.

on the bottom arm. The top knee is bent, angling the front of the patient's body slightly toward the floor or ground. This position, also referred to as the *left lateral recumbent position*, helps prevent aspiration of vomitus. This is discussed in greater detail in Chapter 11, *Airway Management*.

Abbreviations, Acronyms, and Symbols

Medical abbreviations, acronyms, and symbols are types of shorthand used to communicate in the medical world. They evolve for the same reason we abbreviate words in text messages and chats—they allow us to communicate faster. However, in patient care, it is important not to trade speed for accuracy. To minimize misinterpretation and errors, use only commonly understood acronyms and other abbreviations.

All acronyms are abbreviations, but not all abbreviations are acronyms. When you shorten a word using an abbreviation, you pronounce each letter of the abbreviation separately. For example,

emergency medical technician is abbreviated “EMT,” pronounced E–M–T. Acronyms form shortened words from the initials of several words to produce a new word. Acronyms and other abbreviations are sometimes combined to shorten a phrase. For example, the acronym for Urban Search and Rescue, USAR, is pronounced “U-sar.”

An abbreviation is still considered an acronym if it is pronounced as a word, even if the word formed is not part of the English language. An example is HIPAA, short for the Health Insurance Portability

Words of Wisdom

In addition to medical terminology, the population of a specific geographic area can have its own slang or regional jargon. Familiarize yourself with this language to improve your communication when responding to calls in these locations. For example, in the south many older adults refer to diabetes as “the sugars” and hypertension as “high blood.”

and Accountability Act, a law that protects patients' privacy. This abbreviation is classified as an acronym because it is pronounced "hippa," not spelled out letter by letter. DEA, on the other hand, is not considered an acronym because it is spelled out as "D-E-A," rather than pronounced "dee-yuh."

Medical Abbreviations

Abbreviations take the place of the words they represent, to shorten patient care notes or other documentation. Some acronyms have become a common part of the English language. ASAP, for example, stands for "as soon as possible," but is commonly spoken as its own word. Medical abbreviations can be extremely useful for documentation purposes, but they must be consistent with those approved for use in your EMS system.

Error-Prone Abbreviations

The Joint Commission and the Institute for Safe Medication Practices (ISMP) have each published a "do not use" list of abbreviations they believe to be especially prone to misinterpretation.^{1,2} Serious errors can occur when an abbreviation is not interpreted as intended. For example, "HS" on a prescription can mean either "hour of sleep" (take at bedtime) or "half strength." To avoid such errors,

Safety

Be very careful with *look alike, sound alike* drug names. Pay close attention to labels to ensure you accurately write down the names. Some common mistakes are listed below. Each drug is different, yet each can be confused because of similar spelling and/or pronunciation:

- Zantac – Xanax
- Toradol – Tegretol
- Clonazepam – Lorazepam
- Alprazolam – Lorazepam
- Amiodarone – Amrinone
- Celebrex – Celexa
- Sinequan – Singulair
- Prozac – Prilosec

some agencies limit the use of abbreviations or do not allow abbreviations at all.

Trailing Zeros and Naked Decimals

Another common error concerns *trailing zeros* and *naked decimals*. Avoid using trailing zeros after a decimal point. For example, 5.0 mg may be read as 50 mg if the decimal is not seen. The same is true if a leading zero is left off before a decimal. If 0.5 mg is written without the leading zero as .5 mg, then it may be mistaken for 5 mg if the decimal is not seen. Always leave off trailing zeros after the decimal, but include leading zeros prior to the decimal to avoid errors.

Symbols

As with abbreviations, symbols are sometimes used as a shortcut in documentation and other communication. As with abbreviations, it is important that you use only symbols that are widely understood and accepted (**TABLE 5-11**). The symbols > or < may be mistaken for the number "7," the letter "L," or each other. The symbol μ may be mistaken for "mg," resulting in a 1,000 $\times$ overdose. It is better to spell it out than to use symbols that may be misinterpreted.

To protect patients' safety, The Joint Commission requires every hospital to issue a list of approved abbreviations. This list cannot include certain abbreviations prohibited by the commission, such as μ m for micrograms. Each EMS system should also keep a list of approved medical abbreviations available for reporting and documentation purposes. Learn which abbreviations are acceptable in your service area before you use them in a report. For example, some agencies do not use "SOB" as an abbreviation for "shortness of breath." When in doubt, write out the term in full. Accuracy, neatness, and completeness reflect a professional writing style.

Medical Terminology Related to Pharmacology

As an AEMT, you must be familiar with terminology related to medications and medication administration, such as common prefixes (**TABLE 5-12**),

TABLE 5-11 Commonly Used Symbols

°	degrees	/	per
1°	primary, first, first degree	±	plus or minus
2°	secondary, second degree	≠	not equal
↑	increase(d)	>	greater than
↓	decrease(d)	<	less than
α	alpha	≥	greater than or equal to
β	beta	≤	less than or equal to
#	number, pound	?	questionable, possible
∅	null or none	Δ	change
~, ≈	approximately	—	negative
N	normal	♀	female
×2	times two	♂	male

© Jones & Bartlett Learning.

TABLE 5-12 Prefixes Commonly Used in Medication Administration

Prefix Name	Prefix Symbol	Prefix Value
micr/o	mc	1/1,000,000 or 0.000001
milli-	m	1/1,000 or 0.001
centi-	C	100 or 0.01
kil/o	K	1,000
mega-	M	1 million or 1,000,000

© Jones & Bartlett Learning.

common metric conversions used in drug calculation (**TABLE 5-13**), and common medical abbreviations related to pharmacology (**TABLE 5-14**).

Master Tables

TABLE 5-15 through **TABLE 5-18** provide a reference list of prefixes, suffixes, common word roots, and abbreviations.

YOU are the Provider

Part 5

You cover Kevin with a blanket, and during transport, you start an intravenous line in the back of his left hand, using a 20-gauge catheter to infuse normal saline at a TKO rate. You also assess the patient's blood glucose level, which is now 147 mg/dL.

You and your crew transport the patient to a pediatric trauma center, where the child's parents are waiting, and give a verbal report to the receiving staff. Then you sit down in the EMS office to write your report while Matt cleans and restocks the ambulance.

Recording Time: 18 Minutes

Respirations	20 breaths/min
Pulse	98 beats/min
Skin	Cool and clammy
Blood pressure	98/60 mm Hg
Oxygen saturation (Spo₂)	99%
Pupils	PERRLA
Blood glucose level	147 mg/dL

TABLE 5-15 Selected Prefixes Used in Medical Terminology

Prefix	Meaning	Prefix	Meaning
a-	without, lack of	dermat/o	pertaining to the skin
ab-	away from	di-	twice, double
abdomin/o	abdomen	dia-	through, across
acr/o	to, toward	dys-	difficult, painful, abnormal
aden/o	pertaining to a gland	ect/o	out, out from
an-	without, lack of	electro-	pertaining to electricity
ana-	up, back, again	endo-	within
angio-	vessel	enter/o	pertaining to the intestines or gut
ante-	before, forward	epi-	upon, on, above
anti-	against, opposed to	erythr/o	pertaining to anything red or to erythrocytes (red blood cells)
arteri/o	artery	eu-	easy, good, normal
arthro-	pertaining to a joint	ex-	outside
auto-	self	extra-	outside, in addition
bi-	two	gastr/o	pertaining to the stomach
bio-	pertaining to life	glyc/o	sugar
blast/o	germ or cell	gynec/o	pertaining to females or the female reproductive organs
blephar/o	pertaining to an eyelid	hemat/o	pertaining to blood
brady-	slow	hemi-	half
calc-	stone; also heel	hem/o	pertaining to blood
cardi/o	pertaining to the heart	hepat/o	pertaining to the liver
cephal/o	pertaining to the head	hetero-	other, different
cerebr/o	pertaining to the cerebrum, a part of the brain	homo-	same or like
cervic/o	pertaining to the neck or the uterine cervix	hydr/o	water
chole-	pertaining to bile	hyper-	over, excessive
chondr/o	pertaining to cartilage	hypo-	under, deficient
circum-	around, about	hyster/o	pertaining to the uterus
contra-	against, opposite	infra-	below
cost/o	pertaining to a rib	inter-	between
cyan/o	blue	intra-	within
cyst/o	pertaining to the bladder or any fluid-containing sac	iso-	equal
cyt/o	pertaining to a cell	latero-	side
de-	down from

TABLE 5-15 Selected Prefixes Used in Medical Terminology (*continued*)

Prefix	Meaning	Prefix	Meaning
leuk/o	pertaining to anything white or to leukocytes (white blood cells)	phag/o	pertaining to eating, ingesting, or engulfing
lith/o	pertaining to a stone	pharyng/o	pertaining to the throat, or pharynx
macro-	large	phleb/o	pertaining to a vein
mal-	bad or abnormal	pneum/o	pertaining to respiration, the lungs, or air
medi-	middle	poly-	many
mega-	large	post-	after, behind
melan-	black	pre-	before
mening/o	pertaining to a membrane, particularly the meninges	pro-	before, in front of
micro-	small	proct/o	pertaining to the rectum
mono-	one	pseudo-	false
myel/o	pertaining to the spinal cord, the bone marrow, or myelin	psych/o	pertaining to the mind
my/o	pertaining to muscle	pulm/o	pertaining to the lung
nas/o	pertaining to the nose	pur-	pertaining to pus
neo-	new	pyel/o	pertaining to the kidney or pelvis
nephr/o	pertaining to the kidney	py/o	pertaining to pus
neur/o	pertaining to nerves or the nervous system	quadr/i	four
noct-	night	quart-	fourth, four
olig/o	little, deficient	quat-	four
oophor/o	pertaining to the ovary	retr/o	backward or behind
ophthalm/o	pertaining to the eye	rhin/o	pertaining to the nose
orchid/o	pertaining to the testicles	salping/o	pertaining to a tube
orchi/o	pertaining to the testicles	scler/o	hard; also means pertaining to the sclera of the eye
oro-	pertaining to the mouth	semi-	half or partial
ortho-	straight or normal	sub-	under, moderately
oste/o	pertaining to bone	supra-	above
ot/o	pertaining to the ear	tachy-	fast
para-	by the side of	therm-	pertaining to temperature
path/o	pertaining to disease	thorac/o	pertaining to the chest
per-	through	trans-	across
peri-	around	tri-	three
		uni-	one
		vas/o	vessel

TABLE 5-16 Selected Suffixes Used in Medical Terminology

Suffix	Meaning	Suffix	Meaning	Suffix	Meaning
-algia	pertaining to pain	-logy	science of	-ptosis	drooping
-asthen/o	weakness	-lysis	decline, disintegration, or destruction	-rrhage or -rrhagia	abnormal or excessive flow or discharge
-blast	immature cell	-megaly	enlargement of	-rrhaphy	suture of; repair of
-cele	a tumor or swelling	-oma	tumor	-rrhea	flow or discharge
-centesis	a procedure in which an organ or body cavity is punctured, often to drain excess fluid or obtain a sample for laboratory analysis	-osis	a disease process (see also -sis)	-scope	instrument for examination
-cyte	cell	-ostomy	surgical creation of an opening, or hole	-scopy	examination with an instrument
-ectomy	surgical removal of	-otomy	surgical incision	-sis	a process, action, or condition
-emia	pertaining to the presence of a substance in the blood	-pathy	pertaining to disease or a system for treating disease	-taxis	order, arrangement of
-genic	causing	-phobia	an irrational fear	-trophic	nutrition
-gram	record (as in written documentation or results of a study)	-plasty	plastic or reconstructive surgery	-uria	pertaining to a substance in the urine or the condition so indicated
-graph	a record or the instrument used to create the record	-plegia	pertaining to paralysis		
-itis	inflammation	-pnea	pertaining to breathing		

TABLE 5-17 Selected Word Roots and Combining Forms Used in Medical Terminology

Word Root	Meaning	Word Root	Meaning
acou-	pertaining to hearing	edema	swelling
adip-	fat	esthesi/o	pertaining to sensation or perception
alb-	white	febr-	fever
alges-	pertaining to pain	flex	bend
andr-	male	foramen	opening
aort/o	pertaining to the aorta, the large artery exiting from the left ventricle of the heart	fract-	break
aqua-	water	gest-	carry, produce, congestion
asphyxia	lack of oxygen or excess of carbon dioxide in the body that results in unresponsiveness	gno-	know
asthen-	weak	-gram	something written or recorded
audi-	to hear	graph	write, record
bronch-	windpipe	humer/o	pertaining to the humerus, the long bone of the upper arm
bucc-	cheek	idi-, idi/o	separate, distinct or pertaining to the self
bursa	pouch or sac	iod/o	iodine
callus	hard, thick skin; also a lattice of connective tissue that forms during the healing process after a fracture	lact/o	milk
capn/o	carbon dioxide	lingu/o	tongue
carcin/o	cancer	men-	month
carotid	pertaining to the great arteries of the neck	ocul/o	eye
carp/o	pertaining to the carpus, or wrist	ov-	egg
cent/i	a number prefix in the metric system; one-hundredth or 100	palpate	to examine by touch
cent/e	to puncture (a body cavity)	ped-	child or foot
cili-	eyelid	percuss	to examine by striking
cleid/o	clavicle	phagia	pertaining to eating or swallowing
cubitus	elbow	phasia	pertaining to speech
cycl-	circle or cycle	phot/o	light
digit	finger or toe	pleur-	rib, side
		pod-	foot
		pto-	fall
		ptyal-	saliva
		pyr-	fire

Word Root	Meaning	Word Root	Meaning
radius	the forearm bone on the thumb side; also a line from the center of a circle or sphere to the edge	stoma	any small opening on the surface of the body, such as a pore; also, the opening created in the abdominal wall for the passage of urine or feces
ren-	kidney	stature	height
retina	Inner layer of the eye containing the optic nerve	stern/o	sternum (breastbone)
sangu/i	blood	stoma	any small opening on the surface of the body, such as a pore; also, the opening created in the abdominal wall for the passage of urine or feces
seb/o	pertaining to sebum, a fatty secretion of the sebaceous glands	stature	height
sect-	cut	stern/o	sternum (breastbone)
seps-	literally means “decay”; refers to the presence of microorganisms or toxins in the blood, or to the toxic condition that their presence causes in the body	stoma	any small opening on the surface of the body, such as a pore; also, the opening created in the abdominal wall for the passage of urine or feces
sept-	wall, divider; also refers to the number seven	tact-	touch
ser/o	pertaining to serum, the clear portion of body fluids, including blood	tetra-	four
sin/o	pertaining to a cavity, channel, or hollow space	tom/o	cut
som/a or somat/o	body or soma	toxic	poisonous
spir-	coil	trich-	hair
stasis	slowing or stopping of the normal flow of a fluid, such as blood	ur-	urine
stature	height	varic-	varicose vein
stern/o	sternum (breastbone)	vertigo	a disordered sensation in which one's own body or the surroundings are perceived as moving
stoma	any small opening on the surface of the body, such as a pore; also, the opening created in the abdominal wall for the passage of urine or feces	viscer-	internal organs
stature	height	viscum	sticky
stern/o	sternum (breastbone)	xen/o	foreign (material)
		xer-	dry

TABLE 5-18 Common Abbreviations in Medical Terminology^a

Abbreviation	Meaning	Abbreviation	Meaning
A&P	anatomy and physiology	AV	atrioventricular
ā	before	BBB	bundle branch block
AAA	abdominal aortic aneurysm	BGL	blood glucose level
abd	abdomen	bid/b.i.d./BID	twice daily
ABCDE	airway, breathing, circulation, disability, and exposure	BKA	below-the-knee amputation
ac	before meals	BM	bowel movement
ACLS	advanced cardiac life support	BMD	bag-mask device
ACS	acute coronary syndrome	BMV	bag-mask ventilation
ADL	activities of daily living	BP, B/P	blood pressure
ad lib	as desired	BPM	beats per minute
AED	automated external defibrillator	BS	blood sugar, breath sounds, bowel sounds, bachelor of science (degree)
AF, A-fib, A fib, AFib	atrial fibrillation	BSA	body surface area
AICD	automatic implantable cardioverter-defibrillator	BVM	bag-valve mask
AIDS	acquired immunodeficiency syndrome	bx, Bx	biopsy
AK	above the knee	ċ	with
AKA	above-the-knee amputation	°C	degrees Celsius (centigrade)
AMA	against medical advice	CA	cancer, carcinoma, cardiac arrest, chronologic age, coronary artery, cold agglutinin
amb	ambulatory	CABDE	circulation, airway, breathing, disability, and exposure
AMI	acute myocardial infarction	CABG	coronary artery bypass graft
AMS	altered mental status	CAD	coronary artery disease
ant	anterior	CBC	complete blood cell count
AO × 4, A/O × 4, A&O × 4	alert and oriented to person, place, time, and event	CC or C/C	chief complaint
AP	anteroposterior, front-to-back, action potential, angina pectoris, anterior pituitary, arterial pressure	CCU	coronary care unit or critical care unit
ARDS	adult respiratory distress syndrome or acute respiratory distress syndrome	<i>C diff</i>	<i>Clostridium difficile</i>
ASA	aspirin (acetylsalicylic acid)	cm	centimeter
ASHD	arteriosclerotic or atherosclerotic heart disease	CN	cyanide
		CNS	central nervous system
		c/o	complains of
		CO	cardiac output, carbon monoxide

Abbreviation	Meaning	Abbreviation	Meaning
CO ₂	carbon dioxide	ED	emergency department, erectile dysfunction
COLD	chronic obstructive lung disease	EDC	estimated date of confinement
COPD	chronic obstructive pulmonary disease	EDD	expected (estimated) date of delivery
CP	chest pain, chemically pure, cerebral palsy	EEG	electroencephalogram
CPAP	continuous positive airway pressure	EKG	electrocardiogram (the “k” comes from the German word “Elektrokardiogramm”)
CPR	cardiopulmonary resuscitation	ENT	ears, nose, and throat
CR	capillary refill	EOC	Emergency Operations Center
CRNA	certified registered nurse anesthetist	ER	emergency room
CRT	capillary refill time, cathode ray tube	ET, ETT	endotracheal, endotracheal tube
CSF	cerebrospinal fluid	ETA	estimated time of arrival
CT	computed tomography	ETCO ₂	end-tidal carbon dioxide
CVA	cerebrovascular accident	ETOH	ethyl alcohol
DM	diabetes mellitus	°F	degrees Fahrenheit
DNR	do not resuscitate	Fio ₂	fraction of inspired oxygen
DOA	dead on arrival	FBS	fasting blood sugar
DOB	date of birth	Fe	iron
DOD	date of death	FHR	fetal heart rate
DOE	dyspnea on exertion	FHx	family history
DON	director of nursing	fl or fld	fluid
DPT	Diphtheria and pertussis and tetanus toxoids vaccine, Doctor of Physical Therapy	fx	fracture
DSD	dry sterile dressing	GB	gallbladder
DtaP	diphtheria and tetanus toxoids and acellular pertussis vaccine	GCS	Glasgow Coma Scale
DTP	diphtheria and tetanus toxoids and pertussis vaccine	GERD	gastroesophageal reflux disease
DTs	delirium tremens	GI	gastrointestinal
DVT	deep venous thrombosis	GSW	gunshot wound
Dx	diagnosis	GTT	glucose tolerance test
EBL	estimated blood loss	GYN, gyn	gynecology
ECG	electrocardiogram	GU	genitourinary
		h	hour, hours
		H&P	history and physical exam
		HA	headache

(continues)

TABLE 5-18 Common Abbreviations in Medical Terminology^a (*continued*)

Abbreviation	Meaning	Abbreviation	Meaning
Hb, Hgb	hemoglobin	L	liter
HBV	hepatitis B virus	lac, LAC	laceration
HCV	hepatitis C virus	lb	pound, pounds
HCVD	hypertensive cardiovascular disease	LE	lower extremity, left eye, lupus erythematosus
HF	heart failure	LLL	left lower lobe (of the lung)
HH	hiatus hernia	LLQ	left lower quadrant (of the abdomen)
HIV	human immunodeficiency virus	L/M, LPM	liters per minute
H ₂ O	water	LMP	last menstrual period
HPI	history of present illness	LOC	level of consciousness, loss of consciousness
HPV	human papilloma virus	LOM	loss of motion
HR	heart rate	LUL	left upper lobe (of the lung)
hr	hour, hours	LUQ	left upper quadrant (of the abdomen)
HTN	hypertension	LVAD	left ventricular assist device
Hx	history	MAE	moves all extremities
I&O	intake and output	MAEW	moves all extremities well
ICP	intracranial pressure	mcg	microgram
ICS	incident command system, intercostal space	mg	milligram
ICU	intensive care unit	MI	myocardial infarction
IDDM	insulin-dependent diabetes mellitus	MICU	mobile intensive care unit; medical intensive care unit
IHD	ischemic heart disease	min	minute
IM	intramuscular	mL	milliliter
IMS	incident management system	mm	millimeter
IO	intraosseous	mm Hg	millimeters of mercury
IPPB, IPPV	intermittent positive pressure breathing, intermittent positive pressure ventilation	MOI	mechanism of injury
IUD	intrauterine (contraceptive) device	MRI	magnetic resonance imaging
IV	intravenous	MRSA	methicillin-resistant <i>Staphylococcus aureus</i>
JVD	jugular venous distention	MVA	motor vehicle accident
kg	kilogram	MVC	motor vehicle crash
KVO	keep vein open		

Abbreviation	Meaning	Abbreviation	Meaning
MVP	mitral valve prolapse	OPA	oropharyngeal airway
NA, N/A	not applicable	OR	operating room
NAD	no apparent distress, no appreciable disease	oz	ounce
NC	nasal cannula	̄p	after
NG	nasogastric (tube)	PA	physician assistant
NICU	neonatal intensive care unit	pc	after meals
NIDDM	non–insulin-dependent diabetes mellitus	PCI	percutaneous coronary intervention
NKA	no known allergies	Pco ₂	partial pressure of carbon dioxide
NA, N/A	not applicable	PDR	<i>Physicians' Desk Reference</i>
NAD	no apparent distress, no appreciable disease	PE	pulmonary embolism, physical examination
NC	nasal cannula	PEARL or PERL	pupils equal and reactive to light
NG	nasogastric (tube)	PEARLA	pupils equal and reactive to light and accommodation
NICU	neonatal intensive care unit	PEARRL	pupils equal and round, regular in size, react to light
NIDDM	non–insulin-dependent diabetes mellitus	ped or peds	pediatric
NKA	no known allergies	PEEP	positive end-expiratory pressure
NKDA	no known drug allergies	PERRL	pupils equal, round, and reactive to light
NP	nurse practitioner	PERRLA	pupils equal, round, and reactive to light and accommodation
NPA	nasopharyngeal airway	PID	pelvic inflammatory disease
NPO	nil per os (nothing by mouth)	PMH	past medical history
NRB, NRBm	nonbreathing mask	PND	paroxysmal nocturnal dyspnea
NS	normal saline	po	per os (by mouth)
NSR	normal sinus rhythm	PO	postoperative, "post op"
NTG	nitroglycerin	PRN	pro re nata (as needed)
N/V, N&V	nausea and vomiting	psi	pounds per square inch
N/V/D	nausea, vomiting, and diarrhea	PSVT	paroxysmal supraventricular tachycardia
O ₂	oxygen	PT	physical therapy, prothrombin time
OB	obstetrics	pt	patient
OBS	organic brain syndrome	PTA	prior to admission, plasma thromboplastin antecedent
OD	overdose, right eye, optical density, outside diameter, doctor of optometry	PTT	partial thromboplastin time
OP	outpatient		

(continues)

TABLE 5-18 Common Abbreviations in Medical Terminology^a (*continued*)

Abbreviation	Meaning	Abbreviation	Meaning
PVC	premature ventricular complex, polyvinyl chloride	STEMI	ST-segment elevation myocardial infarction
PVD	peripheral vascular disease	STI	sexually transmitted infection
q̄	every	SUID	sudden unexpected infant death
RA	rheumatoid arthritis, right atrium	SVN	small-volume nebulizer
RAD	reactive airway disease, right-axis deviation	SVT	supraventricular tachycardia
RBC	red blood cell	sym or Sx	symptoms
Rh	Rhesus blood factor, rhodium	T	temperature
RLL	right lower lobe (of the lung)	tab	tablet
RLQ	right lower quadrant (of the abdomen)	TB	tuberculosis
RML	right middle lobe (of the lung)	TBA	to be admitted, to be announced
RN	registered nurse	tech	technician, technologist
R/O	rule out	TIA	transient ischemic attack
ROM	range of motion, rupture of membranes	tid/t.i.d./TID	three times a day
RUL	right upper lobe (of the lung)	Tx	treatment
RUQ	right upper quadrant (of the abdomen)	UA, U/A	urinalysis
Rx	prescription	UE	upper extremity
ś	without	URI	upper respiratory infection
SAH	subarachnoid hemorrhage	UTI	urinary tract infection
SaO ₂	oxygen saturation	VF/V fib/VFib	ventricular fibrillation
SARS	severe acute respiratory syndrome	VRE	vancomycin-resistant enterococcus
SG	supraglottic	VS	vital signs
SICU	surgical intensive care unit	VT/V tach	ventricular tachycardia
SIDS	sudden infant death syndrome	W/	with
SL	sublingual	WBC	white blood cell
SOB	shortness of breath	WMD	weapon of mass destruction
SpO ₂	saturation of peripheral oxygen	WNL	within normal limits
S/S, S&S	signs and symptoms	W/O	without
stat	immediately	wt	weight
		̄x	except
		yo; y.o.; y/o	years old

^a Sometimes abbreviations are written with periods (for example, abd. and a.c.), and sometimes different capitalization might be used and might convey a different meaning. Not all possible meanings for each abbreviation are given in this table. Unless you are certain about the meaning, ask the person who used the abbreviation and do not use it yourself.

YOU are the Provider SUMMARY

1. What is the correct medical term for the position in which the child is lying?

He is lying on his left side, which is the recovery position, also called the *left lateral recumbent position*.

2. How can knowledge of medical terminology assist in your documentation of care for this patient?

Medical terminology is the language of medicine and health care. As an AEMT, you should have a good understanding of medical terminology and be able to identify and use terms correctly. This not only allows you to communicate effectively with other health care providers, but also ensures you use accurate and concise documentation, resulting in better continuity of care.

3. Why would you want to avoid using medical terminology when talking to this patient?

Patients, especially children, are rarely familiar with medical terminology. Therefore, using medical terms during a patient interview will probably lead to misunderstanding and a lack of pertinent information. When you talk with patients, use everyday terms to help improve the likelihood of communicating clearly. As an AEMT, you must also be familiar with terms and phrases that are common in the geographic area in which you work.

4. What are the correct medical terms to describe Kevin's mental status and blood glucose level?

His mental status is documented as AOx4 because he is alert to person, place, time, and event. The appropriate term for a high blood glucose level is *hyperglycemia*. It is formed from the prefix *hyper-* (excessive) + the word root *glyc/o* (glucose) + the suffix *-emia* (pertaining to the blood).

5. How would you document that the patient has no medication allergies?

The correct abbreviation for "no known drug allergies" is *NKDA*.

6. Describe the position of the patient's head injury.

His injury is on the right side of his forehead, just above his eye. Because *superior* is the term for above and *orbit* is the eye socket, it would be documented as *superior to the right orbit*.

7. What is the abbreviation for the abdominal quadrant that is tender to the touch?

The abdomen is divided into quadrants by two imaginary lines intersecting at the umbilicus. The area where Kevin reports having pain is the upper quadrant on the right side. The abbreviation is *RUQ*.

8. Why is knowledge of anatomy pertinent when assessing and treating this patient?

Familiarity with the structures and functions of the body systems will allow you to better assess a patient as well as predict potential complications resulting from occult injuries (those not visible to the eye). In this instance, if you know what organs are located in the RUQ, you can predict possible injuries, which allows for a greater index of suspicion resulting in more appropriate treatment and transport to the proper facility.

9. What is the medical term for clammy skin?

The term for clammy skin associated with signs of shock is *diaphoresis*.

10. What is the medical term for a phenomenon (such as pain, swelling, or a rash) affecting both sides of the body?

Many body structures are bilateral, and certain medical conditions tend to occur either unilaterally or bilaterally. A phenomenon affecting or appearing on both sides of the midline is said to be *bilateral*.

EMS Patient Care Report (PCR)

Narrative				

9-1-1 dispatch for a male patient who fell. On arrival at the scene, found a 7-y/o male lying left lateral recumbent in fetal position and holding abdomen; comforted by teacher. Teacher states pt fell approximately 6 feet from top of playground equipment and has not been moved. Patient AO×4, c/o pain in right upper quadrant. Presents with a golf ball-size hematoma superior to the right orbit with small laceration—bleeding controlled. Patient states he has been “dizzy” this morning, causing his fall. PERRLA, slightly tachycardic and tachypneic. Hx—IDDM, for which he takes insulin and has NKDA. Teacher states blood glucose level was 183 mg/dL on arrival this a.m. Pt states he ate and took insulin this a.m. Further assessment of patient’s abdomen revealed that it was soft, but very tender to palpation of the RUQ, with discoloration of the area. Spinal motion restriction established on LSB with c-collar and CID and loaded into ambulance for transport to the pediatric trauma center. En route, vital signs reassessed and noted above, breath sounds clear and equal bilaterally, skin cool and diaphoretic, glucose 147 mg/dL. Pt covered to maintain warmth, head wound bandaged, and 20 g IV left dorsal hand with normal saline at TKO rate. Reassessment of abdomen finds increased tenderness and darker discoloration. Met patient’s parents and transferred care of patient to receiving hospital without incident. Written report completed and ambulance cleaned and restocked. Departed the hospital and returned to service.

End of report

Prep Kit

Ready for Review

- Knowledge of medical terminology is essential for health care team members to communicate effectively and document calls.
- You must be able to identify superficial landmarks of the body. These landmarks indicate which structures lie underneath the skin, so you can perform an accurate patient assessment.
- Understanding how terms are formed, and the definitions for the various parts of a medical term, will help you determine the meaning of an unknown term.
- To strengthen your grasp of medical terminology, become familiar with commonly used medical eponyms, homonyms, and antonyms, as well as symbols and terms used in pharmacology.
- A prefix is the part of a term that appears at the beginning of a word. It generally describes location and intensity of the word root that follows.
- A suffix is placed at the end of a word to change the original meaning. In medical terminology, a

suffix usually indicates a procedure, condition, disease, or part of speech.

- The word root is the foundation of the term. It establishes the basic meaning of the word.
- A combining vowel is the part of a term that connects a word root to a suffix or other word root to make it easier to pronounce.
- Prefixes can also indicate numbers or direction. Word roots can also describe color.
- Compound words are words that contain more than one word root.
- To make some terms plural, an s is added to the term. Other terms use other plural forms.
- Anatomic position refers to the body in a standing position, facing you, with arms at the sides and palms facing forward. Patient position is the position in which the patient is found when you arrive on scene.
- Anatomic planes of the body include coronal, transverse, and sagittal (lateral).
- Directional terms indicate distance and direction from the midline. These include right, left, superior, inferior, lateral, medial, proximal, distal, superficial, deep, ventral, dorsal, anterior, posterior, palmar, plantar, and apex.
- Terms related to movement and position include flexion, extension, adduction, abduction, supination, pronation, and rotation.
- Other directional terms relate to a position on one or both sides of the body. Such terms include bilateral, unilateral, ipsilateral, and contralateral.
- The concept of quadrants is useful in medical terminology. The abdomen is commonly categorized into quadrants to help specify an area of pain or injury.
- Abbreviations, acronyms, and symbols are used as shorthand to communicate and document in a concise manner. To avoid potentially dangerous misinterpretation of your documentation, ensure you use only abbreviations that are commonly understood in your system; avoid using abbreviations that are not recommended.

Vital Vocabulary

abduction Movement of a limb *away* from the midline of the body.

adduction Movement of a limb *toward* the midline of the body.

anatomic position The position of reference, in which the patient stands facing you, arms at the side, with the palms of the hands facing forward.

anterior The front surface of the body; the side facing you in the anatomic position.

anteroposterior axis The axis that runs perpendicular to the coronal plane.

antonyms Pairs of word roots, prefixes, or suffixes that have opposite meanings.

apex (plural apices or apexes) The pointed extremity of a conical structure.

bilateral In anatomy, a body part or condition that appears on both sides of the midline.

combining form A word root followed by a vowel.

combining vowel The vowel used to combine two word roots or a word root and a prefix or suffix.

compound word A word containing more than one word root.

contralateral On the opposite side of the body.

coronal plane An imaginary plane in which the body is cut into front and back portions.

cross section The product of slicing an object crosswise, perpendicular to its long axis.

deep Farther inside the body and away from the skin.

distal Farther from the trunk and nearer to the free end of the extremity.

dorsal The posterior surface of the body, including the back of the hand.

eponym The name of a disease, device, procedure, or drug that is based on the person who invented, discovered, or first described it.

extension The straightening of a joint.

external rotation Rotating an extremity at its joint away from the midline.

flexion The bending of a joint.

Fowler position A sitting position, with the head elevated at a 90° angle (sitting straight upright).

homonyms Words that sound alike but are spelled differently and have different meanings.

horizontal axis The axis that runs perpendicular to the sagittal plane; also called the mediolateral axis.

hyperextension Extension beyond the normal range of motion.

hyperflexion Flexion beyond the normal range of motion.

inferior Below what is indicated; closer to the feet.

internal rotation Rotating the anterior surface of an extremity toward the midline.

ipsilateral On the same side of the body.

lateral In anatomy, parts of the body that lie farther from the midline.

longitudinal axis The axis that runs perpendicular to the transverse plane.

longitudinal section The view of an object cut along its long axis.

medial In anatomy, parts of the body that lie closer to the midline.

midsagittal plane (midline) An imaginary vertical line drawn from the middle of the forehead through the nose and the umbilicus (navel) to the floor.

palmar The position in which the palm of the hand is facing forward when in the anatomic position.

plantar The sole or bottom surface of the foot.

posterior In anatomy, the back surface of the body; the side away from you in the standard anatomic position.

prefix The word part that appears before a word root, changing the meaning of the term.

pronation The act of rotating the forearms in a palms-down manner.

prone Lying flat, facedown.

proximal Closer to the trunk.

quadrants The four sections of the abdominal cavity shown by two imaginary lines intersecting at the umbilicus, dividing the abdomen into four equal areas.

range of motion The full distance that a joint can be moved.

sagittal (lateral) plane A plane of the body that passes vertically from front to back, dividing the body into left and right portions.

suffix The word part that comes after the word root, at the end of the term.

superficial Closer to or on the surface of the skin.

superior Above what is indicated; closer to the head.

supination Turning the palms upward (toward the sky).

supine Lying faceup.

synonyms Pairs of word roots, prefixes, or suffixes that have the same or almost the same meaning.

topographic anatomy Superficial landmarks of the body that serve as guides to the structures that lie beneath them.

transverse (axial) plane An imaginary plane passing horizontally through the body at the waist, dividing it into top and bottom halves.

unilateral Occurring or appearing on only one side of the body.

ventral The anterior surface of the body.

word root The foundation of a word; establishes the basic meaning of a word.

Chapter 6

Lifting and Moving Patients

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Preparatory

Applies fundamental knowledge of the EMS system, safety/well-being of the AEMT, medical/legal and ethical issues to the provision of emergency care.

Workforce Safety and Wellness

- Lifting and moving patients (pp 217–255)

KNOWLEDGE OBJECTIVES

1. Describe the technical skills and general considerations that are required of the advanced emergency medical technician (AEMT) during patient packaging and patient handling. (pp 216–217)
2. Describe how following proper patient lifting and moving techniques helps prevent work-related injuries. (pp 217–218)
3. Describe the guidelines for properly lifting a patient, using a power grip, a draw sheet, or blanket. (pp 219–221)
4. Summarize the general considerations required to safely move patients without causing them further harm while simultaneously protecting the AEMT from injury. (pp 221–225)
5. Describe the guidelines and safety precautions AEMTs should follow when lifting and carrying a patient on a stretcher or backboard, and how to avoid common mistakes. (pp 225–228)
6. Describe specific situations in which emergency moves or urgent moves (rapid extrication) may be necessary for moving a patient; include how each move is performed. (pp 228–235)
7. Describe specific situations in which nonurgent moves may be necessary for moving a patient; include how each move is performed. (pp 235–241)
8. Discuss special considerations when moving and transporting geriatric patients and the guidelines to follow when lifting and moving geriatric patients. (pp 241–242)
9. Define the term *bariatrics*; include the guidelines for lifting and moving bariatric patients. (p 243)
10. Name 11 patient-moving devices; include how each one is used to move a patient. (pp 243–253)
11. Explain the importance of equipment decontamination in the prevention of disease transmission. (p 253)
12. Describe proper patient positioning with the following medical conditions: (pp 253–254)
 - Unresponsive patients without suspected spine injury
 - Patients with chest pain, discomfort, or difficulty breathing

- Patients with suspected spine injury
- Pregnant patients with hypotension
- Patients who are nauseated or vomiting

13. Discuss situations that may require the use of medical restraints on a patient; include the guidelines and safety considerations regarding use. (pp 254–255)

SKILLS OBJECTIVES

1. Demonstrate the body mechanics and principles required for safe reaching and pulling, including the safe reaching technique used for performing log rolling. (pp 217–225)
2. Demonstrate a power lift to lift a patient. (p 220, Skill Drill 6-1)
3. Demonstrate using a power grip. (p 221)
4. Demonstrate the two-person body drag. (p 223, Skill Drill 6-2)
5. Demonstrate how to log roll a patient. (p 224)
6. Demonstrate the diamond carry to move a patient. (p 227, Skill Drill 6-3)
7. Demonstrate the one-handed carrying technique to move a patient. (p 229, Skill Drill 6-4)
8. Demonstrate how to perform an emergency or urgent move such as a one-person technique for removing an unresponsive patient from a vehicle. (p 231, Skill Drill 6-5)
9. Demonstrate the rapid extrication technique to move a patient from a vehicle. (pp 233–234, Skill Drill 6-6)
10. Demonstrate the direct ground lift to lift a patient. (p 236, Skill Drill 6-7)
11. Demonstrate the extremity lift to move a patient. (p 237, Skill Drill 6-8)
12. Demonstrate the direct carry to move a patient. (p 238, Skill Drill 6-9)
13. Demonstrate how to use the draw sheet method to transfer a patient onto a stretcher. (p 239, Skill Drill 6-10)
14. Demonstrate the use of a scoop stretcher to move a patient. (p 240, Skill Drill 6-11)
15. Demonstrate how to lift a patient from the ground. (p 241, Skill Drill 6-12)
16. Demonstrate how to move a patient from a chair to a stair chair. (p 242, Skill Drill 6-13)
17. Demonstrate how to load a stretcher into an ambulance. (p 247, Skill Drill 6-14)
18. Demonstrate how to carry a patient on stairs using a stair chair. (p 251, Skill Drill 6-15)
19. Demonstrate a patient carry to move a patient up or down stairs. (p 252, Skill Drill 6-16)
20. Demonstrate the correct use of medical restraints on a patient. (p 254)

Introduction

In the course of a call, you will have to move the patient several times when assessing, treating, and transporting the patient to the emergency department (ED). Often, you will have to move the patient into a different position or location. These moves will likely involve the use of a stretcher, backboard, or other devices. Once you have assessed the patient and provided emergency medical care, you and your team will have to move the patient from the scene to the ambulance and from the ambulance to the ED bed. To avoid injury to the patient, yourself, and your partners, you need to learn how to lift and carry the patient properly and safely, using proper body mechanics and a power grip.

To be able to move a patient safely and properly in the various situations that you will encounter in the field, you need to learn how to perform emergency body drags and lifts, rapidly move a patient from a vehicle onto the stretcher, assist a patient from a chair or bed onto the stretcher, and lift a patient from the floor onto the stretcher. In addition, you may need to carry a patient up or down stairs. You and your team need to know how to place a patient with a suspected spinal injury onto an immobilization device and package patients with and without suspected spinal injury. At times, you and your team will need to move a patient who is very heavy or carry a patient on a trail or across rugged terrain. You and your team should be familiar with the special techniques for lifting and moving patients, and should practice them often.

Lifting and carrying are dynamic processes. To ensure no person suddenly bears unexpected, dangerous weight and to reduce the risk of injury to a provider or a patient, you must know where all providers should be positioned and how to give and receive lifting commands so all parties act simultaneously. You need to know how to prepare patient-moving devices, such as a wheeled ambulance stretcher, stair chair, backboard, scoop stretcher, folding ambulance stretcher, basket stretcher, flexible stretcher, and any other equipment your service may carry. Most important, you need to know how and when to use them.

Training and practice are required to use all the equipment that is described in this chapter. You must master the skills necessary to use each device and understand its advantages and limitations. Practice each technique with your team often so you can perform the move quickly, safely, and efficiently. After each patient transfer, you and your team should evaluate the appropriateness of the technique that you used and your technical skill in completing the transfer. You must also ensure you maintain your equipment according to the manufacturer's instructions. Using clean, well-maintained equipment is a critical part of

providing high-quality patient care. This chapter covers a review of body mechanics, lifting, carrying, and reaching techniques and the principles of moving patients, including emergency, urgent, and nonurgent moves. In addition, different types of patient-moving equipment and patient positioning are discussed in detail.

Body Mechanics

Anatomy Review

When you are lifting, moving, or transferring patients, the need for proper body mechanics should remain paramount. When the person is standing upright, the individual weight-bearing vertebrae are stacked on top of each other and aligned over the sacrum. The sacrum is the mechanical weight-bearing base of the spinal column and the fused central posterior section of the pelvic girdle. The shoulder girdle rests on the rib cage and is supported by the vertebrae that lie inferior to it. The arms are connected to and hang from the shoulder girdle.

When a person is standing upright, the weight of anything being lifted and carried in the hands is reflected onto the shoulder girdle, the rib cage, the spinal column inferior to it, the pelvis, and then the legs (**FIGURE 6-1**). In lifting, if the shoulder girdle is aligned over the pelvis and the hands are held close to the legs, the force that is exerted against the spine occurs in an essentially straight line down the strong, stacked vertebrae in the spinal column. Therefore, with the back properly maintained in an upright position, very little strain occurs against the muscles and ligaments that keep the spinal column in alignment, and significant weight can be lifted and carried without injury to the back (**FIGURE 6-2**). However, you may injure your back if you lift while

Words of Wisdom

Patient **packaging** and handling are technical skills that you will learn and perfect through practice and training. Every year, a substantial number of emergency medical services (EMS) personnel are injured when they attempt to lift and move patients. Even when you are lifting, moving, or transferring relatively lightweight patients, the need for proper body mechanics should remain paramount.

YOU are the Provider

Part 1

Your ambulance is requested to help in directly admitting a patient from a private residence to the local hospital's surgical unit. Your patient is a bedridden older adult male who weighs approximately 325 pounds (147 kg). He is alert and oriented, but he is unable to assist in being moved to the stretcher. He has an indwelling urinary catheter in place.

1. What additional resources may be needed to move this patient?
2. How will you move this patient from his bed to the stretcher?

FIGURE 6-1 When you are standing upright, the weight of anything that you lift and carry in your hands is borne by the shoulder girdle, the spinal column, the pelvis, and the legs.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

leaning forward, or even if straight, bent significantly forward at the hips (**FIGURE 6-3**). With the back in either of these positions, the shoulder girdle lies significantly anterior to the pelvis, and the force of lifting is exerted primarily across, rather than down, the spinal column. When this occurs, the weight is supported by the muscles of the back and ligaments that run from the base of the skull to the pelvis, keeping the spinal column in alignment, rather than by each vertebral body and disk resting on those aligned below it. In addition, the upper spine and torso serve as a lever so that the force that is exerted against the muscles and ligaments in the lumbar and sacral regions, as a result of the mechanical advantage produced, is many times that of the combined weight of your upper body and the object you are lifting. Therefore, the first key rule of lifting is to always keep the back in a straight,

FIGURE 6-2 If your body is properly aligned when you lift, the line of force exerted against the spine occurs in an essentially straight line down the vertebrae. In this way, the vertebrae support the lift.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

FIGURE 6-3 This photo demonstrates an incorrect method of lifting. When this occurs, the muscles of the back, not the vertebral bones themselves, are supporting the lift.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

upright (vertical) position and to lift without twisting or bending. Always face the patient and point your feet in the same direction. After lifting the patient, change the direction of your feet as opposed to twisting or turning from the waist.

Proper Lifting Technique

When you are lifting, spread your legs approximately 15 inches (38 cm) apart (shoulder width) and place your feet so your center of gravity is properly balanced between them. Then, with the back held upright, bring your upper body down by bending the legs into a squat. Once you have properly grasped the patient or stretcher and made any necessary adjustments in the location of your feet, lift the patient by straightening your legs and raising your upper body until you are again standing. Your arms should still be extended. You can then *curl* your forearms if you need to lift higher. This is the same technique used when performing a bicep curl with weights. Because the leg muscles are regularly exercised by walking, climbing stairs, or running, they are well developed and extremely strong. Therefore, as well as being the safest way to lift, lifting by extending the properly placed flexed legs is also the most powerful way to lift. This method is appropriately called a **power lift**. The power lift position is also useful for people who have weak knees or thighs.

One mistake you can make while performing a patient lift is to lift a patient or other heavy object with your arms outstretched. Even if the back is held properly upright, the same adverse force across the spinal column and leverage against the lower back will occur if you lift a heavy object with your arms significantly outstretched. Whenever you are lifting or carrying a patient, hold your arms so your elbows are aligned with the sides of your body. Always keep the weight that you are lifting as close to your body as possible.

Another rule to remember when lifting is to avoid placing lateral force across the spine and sideways leverage against the lower back. If you lift with only one arm or with the arms extended more to one side than the other, more force will be exerted against one side of the shoulder girdle than the other, causing lateral force to be exerted across the spinal column. To prevent this, keep your arms approximately the same distance apart as when hanging at each side of the body, with the weight distributed equally and properly centered between them. If the weight is not balanced between both arms or properly centered between the shoulders when you are preparing to lift, turn your body and/or move to the left or right until the weight is properly balanced and centered. To lift safely and

produce the maximal power lift, take the steps shown in **SKILL DRILL 6-1**.

Reverse these steps whenever you are lowering the stretcher. Always remember to avoid bending at the waist.

Safety

The safety of advanced emergency medical technicians (AEMTs) and patients depends on proper lifting techniques and maintaining a proper hold while lifting and carrying. Loss of grasp by one AEMT may cause injury to another team member and to the patient.

Proper Hold

Your safety, as well as that of the other AEMTs and the patient, depends on the use of proper lifting techniques, having and maintaining a proper hold when lifting or carrying a patient, and being in good physical health. If you do not have proper hold of the stretcher or of the patient in a body lift, you will not be able to bear a proper share of the weight, and there is an increased chance that you can suddenly lose your grasp with one or both hands. If you temporarily lose your grasp with one or both hands, the position and weight distribution of the stretcher changes suddenly, and the other members of the team must quickly reach beyond a safe distance to avoid dropping the patient. As a result, sudden excessive force may be placed across each one's spine, causing lower back injury.

Use the **power grip** to get the maximum force from your hands whenever you are lifting a patient (**FIGURE 6-4**). The arm and hand have their greatest lifting strength when facing palm up. Whenever you grasp a stretcher or backboard, your hands should be at least 10 inches (25 cm) apart. Each hand should be inserted under the handle with the palm facing up and the thumb extended upward. Then, advance the hand until the thumb prevents further insertion and the cylindrical handle lies firmly in the crease of the curved palm. Curl your fingers and thumb tightly over the top of the handle. All your fingers should be at the same angle. To have the proper power grip, make sure the underside of the handle is fully supported on your curved palm with

Skill Drill 6-1 Performing the Power Lift

Step 1

Tighten your back in a normal upright position and lock it in a slight inward curve at the lumbar area. Spread your legs about 15 inches (38 cm) apart, and bend your legs to lower your torso and arms. With your arms extended down, grasp the stretcher or backboard with your hands held palm up and just in front of you. Balance and center the weight between your arms.

© Jones & Bartlett Learning.

Step 2

Reposition your feet as necessary so they are about 15 inches (38 cm) apart with one slightly farther forward and rotated so your center of gravity is properly balanced between your legs. Straddle the object and distribute your weight. Do not bend your knees more than 90°, nor extend your knees past your toes. With your arms extended downward, lift by straightening your legs until you are fully standing. Hold your back upright and ensure your upper body comes up before your hips.

only the fingers and thumb preventing it from being pulled sideways or upward out of the palm.

If you must lift the object higher once you have lifted by extending your legs, you will be able to lift the object higher by using your biceps to “curl” the arms while maintaining the power grip and weight supported in the palms.

Never grasp a stretcher or backboard with your hand placed palm down over the handle. Doing so will cause the weight to be supported by your fingers rather than your palm. This hand orientation places the tips of the fingers and thumb under the handle. If the weight forces them apart, or if the stretcher is pushed suddenly downward in

FIGURE 6-4 To perform the power grip, grasp the handle of the stretcher or backboard with your palms up and your thumbs extending up. Make sure your hands are about 10 inches (25 cm) apart and that your fingers are all at the same angle. The underside of the handle should be fully supported by the palms of your hands.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

the process of moving, you will lose your grasp on the handle.

If possible, use a draw sheet or other approved lifting device so you are not pulling directly on the patient’s skin (discussed later in the chapter). This is especially important when lifting patients who are heavy and/or older. When you are lifting a patient by a sheet or blanket, center the patient on the

sheet and tightly roll up the excess fabric on each side. This produces a cylindrical handle that provides a strong, secure way to grasp the fabric. It is crucial that there is no give in the sheet and that it is kept as taut as possible because a sudden shift of weight as the fabric gives can injure providers.

Directions and Commands

To safely lift and carry a patient, you and your team must anticipate and understand every move, and each move must be executed in a coordinated manner. The team leader should indicate where each team member is to be located and rapidly describe the sequence of steps that will be performed to ensure team members know what is expected of them before they initiate any lifting. If you must lift and move a patient through a number of separate steps, the team leader should first give an abbreviated overview of the steps, followed by a more detailed explanation of each step just before it will occur.

Orders that will initiate the actual lifting or moving or any substantial changes in movement should be given in two parts: a preparatory command and a command of execution. For example, if the team leader says “All ready to stop. STOP!” the “All ready to stop” will get your attention, identify who should act, and prepare you to act; the declarative “STOP!” will indicate the exact moment for execution.

YOU

are the Provider

Part 2

You request additional lifting assistance and clear a path for the stretcher to travel through the living room. The patient states he has several pressure wounds on his back and buttocks and asks you to be careful when moving him. An engine crew arrives and you decide that the best way to move him is to use the draw sheet method.

Recording Time: 2 Minute

Appearance	Alert
Level of consciousness	Alert and oriented
Airway	Patent
Breathing	Nonlabored
Circulation	Skin warm and dry

3.

What are some potential complications when patients are moved improperly?

4.

Should you use an emergency, urgent, or nonurgent move?

5.

What are some of the differences between a normal stretcher and a bariatric stretcher?

Commands of execution should be delivered in a louder voice. Often, a countdown is helpful when you need to lift a patient. To avoid confusion when you countdown, always clarify whether “three” is to be a part of the preparatory command or whether it is to serve as the order to execute. In other words, say, “We’re going to lift on three. One-two-THREE!” or, “I’m going to count to three and then we’re going to lift. One-two-three-LIFT!”

Words of Wisdom

Ensure you are lifting in tandem to prevent injury to the patient or providers. The person calling the move should always announce, “We are going to lift on three,” or, “We are going to count to three and then lift.”

Principles of Safe Reaching and Pulling

When you use a body drag to move a patient, the same basic body mechanics and principles apply as when you move, lift, and carry a patient. Your back should always be locked in a slight curve created by tightening your abdominal muscles, not curved laterally or bent laterally. It should be held in a normal upright position. Avoid any twisting so your vertebrae remain in normal alignment. When you are reaching overhead, avoid hyperextending your back. When you are pulling a patient who is on the ground, always kneel to minimize the distance that you will have to lean over (**FIGURE 6-5A**). To keep your reach within the recommended distance, reach forward and grasp the patient so your elbows are just beyond the anterior part of the torso (**FIGURE 6-5B**). When you are pulling a patient who is at a different height from you, bend your knees until your hips are just below the height of the plane across which you will be pulling the patient. When you are pulling, do not extend your arms more than about 15 to 20 inches (38 to 50 cm) in front of your torso. Reposition your feet (or knees, if kneeling) so the force of pull will be balanced equally between both arms and the line of pull will be centered between them (**FIGURE 6-5C**). Pull the patient by slowly flexing your arms. When you cannot pull further because your hands have reached the front of your torso, stop and move back another 15 to 20 inches (38 to 50 cm). Then, when properly positioned, repeat the steps. Alternate between pulling the patient by flexing your arms and

then repositioning yourself so your arms are again extended with your hands about 15 inches (38 cm) in front of your torso. By not moving simultaneously with the patient, you prevent an undesirable jostling of the patient and the chance that sudden unscheduled force will occur across your spine. You may prevent injury to yourself by avoiding situations that involve strenuous effort lasting more than 1 minute.

Words of Wisdom

It is acceptable to use a belt to assist in moving a patient; however, NEVER rely on belt loops or pockets to attach the belt to. They may rip or tear and result in injury to the patient or providers.

Moving a Patient Across a Bed

If you must drag a patient across a bed, kneel on the bed to avoid reaching beyond the recommended distance. Follow the steps described previously until the patient is within 15 to 20 inches (38 to 50 cm) of the bed's edge. Complete the drag while standing at the side of the bed. Rather than dragging the patient by the clothing, use the sheet or blanket under the patient for this purpose. Roll the bedding

under the patient until it is about 6 inches (15 cm) wider than the patient. Pull on the rolled bedding smoothly and evenly to glide the patient to the bed-side. Watch out for soiled sheets. Wear proper protective equipment as needed.

Unless the patient is on a backboard, transfer the patient from the stretcher to a bed in the ED or the patient's hospital room with a body drag. With the stretcher at the same height as the bed or slightly higher and held firmly against its side, you and another provider should kneel on the hospital bed and, in the manner previously described, drag the patient in increments until the patient is properly centered on the bed. When transferring the patient onto a narrow examining table, rather than kneel on the table, drag the patient while you stand against the opposite side. A third person may need to take both sides of the draw sheet at the head to move the patient safely.

The Two-Person Body Drag

Sometimes during a body drag, you and another provider may have to pull the patient with one of you on each side of the patient. You will have to alter the usual pulling technique to prevent pulling sideways and producing adverse lateral leverage against your lower back. Follow the steps in **SKILL DRILL 6-2** to perform a two-person body drag.

Skill Drill 6-2 Performing a Two-Person Body Drag

© Jones & Bartlett Learning.

Step 1

Position yourself by kneeling on either side of the patient, just beyond the patient's shoulders, facing the patient's groin. You and your lifting partner will each extend one arm across and in front of your chests and grasp the patient's armpit closest to you. With the other arm extended in front and to the side of the patient's torso, you and your partner will grasp the patient's clothing at the beltline.

Step 2

As a unit, raise your elbows and flex your arms to pull the patient lengthwise, as close to the floor as possible.

FIGURE 6-6 When placing a patient onto a backboard from the ground, log roll the patient onto the side. Kneel as close to the patient's side as possible, leaving only enough room so your knees will not prevent the patient from being rolled. Lean forward, keep your back straight and lean solely from the hips. Use your shoulder muscles to help with the roll.

© Jones & Bartlett Learning - Steven Sulewski Photography.

Log Rolling a Patient

Generally, when log rolling a patient onto the side, you will initially have to reach farther than 18 inches (46 cm) (**FIGURE 6-6**). To minimize this distance, kneel as close to the patient's side as possible, leaving only enough room so your knees will not prevent the patient from being rolled. When you lean forward, keep your back straight, and lean solely from the hips. Use your shoulder muscles to help with the roll. To minimize the amount of time you are extended like this and to support the patient's weight, roll the patient without stopping until the patient is resting on the side and braced against your thighs. During a log roll, most experts recommend pulling rather than pushing the patient. This gives you more control of the roll. Local protocols will guide your training in this area. Pulling toward you allows your legs and body to prevent the patient from rolling over completely and from rolling beyond the intended distance.

Rolling a Wheeled Ambulance Stretcher

The wheeled ambulance stretcher is the most commonly used device to move and transport patients. When you are rolling the wheeled ambulance stretcher, ensure it is in the fully elevated position. If you are guiding the stretcher from the foot end,

FIGURE 6-7 Push the stretcher from the head end. If you are guiding the stretcher from the foot end, hold your arms close to your body, and avoid reaching significantly behind you or hyperextending your back. Your back should be locked, straight, and untwisted.

© Jones & Bartlett Learning - Steven Sulewski Photography.

hold your arms close to your body, and avoid reaching significantly behind you or hyperextending your back (**FIGURE 6-7**). Your back should be locked, straight, and untwisted. While you are walking and pulling the stretcher, bend slightly forward at your hips. As you walk, your legs are pulled back with the feet on the ground, your pelvis is moved forward, and the movement of the pelvis is transferred to the stretcher through your straight torso and firmly held arms. Keep the line of the pull through the center of your body by bending your knees.

A second AEMT should guide the head end and assist you by pushing with their arms positioned so the elbows are bent and the hands are about 12 to 15 inches (30 to 38 cm) in front of the torso. To protect your elbows from injury, never push an object with your arms fully extended in a straight line and the elbows locked. When you push with the elbow bent but firmly held from bending further, the strong muscles of the arm serve as a shock absorber if the wheels or foot end of the stretcher strikes an obstacle that causes its progress to be suddenly slowed or stopped. Push from the area of your body

Words of Wisdom

It is far safer to push the stretcher from the ends than to move it sideways. Avoid moving a stretcher sideways if possible.

that is between the waist and shoulder. If the weight you are pushing is lower than your waist, push from a kneeling position, and move forward little by little as needed to stay close to the patient. Do not push or pull from an overhead position.

Lifting and Carrying a Patient on a Backboard or Stretcher

Whenever possible, use a device that can be rolled to move a patient. When moving a wheeled stretcher, pull the foot end of the stretcher while your partner guides it from the head end.

If a wheeled device is not available, make sure you understand and follow certain guidelines for carrying a patient on a stretcher. **TABLE 6-1** shows the guidelines.

When a stretcher must be carried, it is best if four providers are available to carry it. There is more stability with a four-person carry, and the carry requires less strength. One AEMT should be positioned at each corner of the stretcher to provide an even lift. A four-person carry is much safer if the stretcher must be moved over rough ground. If only two AEMTs are available, or if limited space will allow room for only two AEMTs to carry the stretcher, there is a risk that the stretcher will become unbalanced. In a two-person carry, the two AEMTs should stand facing each other, with one person at the head end of the stretcher and the other at the foot end. With this type of carry, one AEMT will have to walk backward.

TABLE 6-1 Guidelines for Carrying a Patient on a Stretcher

- Estimate the weight of both the patient and the associated equipment to be lifted and gauge the limitations of your team’s abilities.
- Coordinate your movements with those of the other team members while constantly communicating with them.
- Do not twist your body as you are carrying the patient.
- Keep the weight that you are carrying as close to your body as possible while keeping your back in a locked-in position.
- Do not bend at the waist; this could hyperextend your back. Instead, flex at the hips, and bend at the knees.

© Jones & Bartlett Learning.

If a patient is supine on a backboard or is lying or in a semi-Fowler position on the stretcher, the patient’s weight is not equally distributed between the two ends of the device. Between 68% and 78% of the body weight of a patient in a horizontal position is in the torso. Therefore, more of the patient’s weight rests on the head half of the device than on the foot half. It is important that you and your team use the correct lifting techniques to lift the stretcher. If possible, all team members should be of the same approximate height and strength.

Weight and Distribution

You should estimate how much the patient weighs before attempting to lift the patient. Commonly, adult patients weigh between 120 and 220 pounds (54 and 100 kg). If you use the correct technique, you and one other AEMT should be able to safely lift this weight. Depending on your individual strength, you and another provider may be able to safely lift an even heavier patient. However, because it is safer to have four providers lift, use four providers whenever the available resources allow. You should know how much you can comfortably and safely lift and should not attempt to lift a proportional weight (the share of the weight that you will bear) that exceeds this weight. If lifting the patient places a strain on you, call for the lifting to be stopped and the patient to be lowered. Then obtain additional help before again attempting to lift the patient. Communicate clearly and frequently with your partner and other providers whenever you are lifting a patient.

Do not attempt to lift a patient who weighs more than 250 pounds (114 kg) with fewer than four providers, regardless of your strength. Protocols should include a method to rapidly summon additional help to lift and carry a patient of such weight or, as in the case of a cardiac arrest, provide and maintain the necessary care in the field and when moving and transporting the patient. In addition, you must know, or be able to find out, the weight limitations of the equipment you are using and how to handle patients who exceed the weight limitations. Special bariatric techniques, equipment, and resources are generally required to move any patient who weighs more than 350 pounds (159 kg) to the ambulance. These resources should be summoned when you arrive on scene and have assessed the situation.

As discussed, more than one-half of a patient's weight is distributed to the head end of the backboard or stretcher. Therefore, the strongest of the available AEMTs should be located at the head end of the device. Even with four or more AEMTs carrying a patient, the strain on the AEMT carrying the head end of the device will be increased when you must negotiate a narrow area or flight of stairs.

In carrying a patient up a flight of stairs, however, proportionally greater weight will be distributed to the AEMT who is carrying the foot end when the backboard or stretcher becomes angled on the incline. You should anticipate this and, in such cases, ensure the two strongest AEMTs are positioned at the head end and foot end of the device. Because of the incline of the stairway, if one AEMT is considerably taller than the other, it will be easier if the shorter one is at the head end and the taller one is at the foot end.

The dynamics that are involved in carrying a patient down a flight of stairs or for any significant distance will not allow you to carry as much proportional weight to safely lift or support the patient during a move onto a nearby backboard or stretcher. Therefore, if you believe you are approaching your maximum lifting capacity as you are moving the patient onto a backboard or stretcher, do not attempt to lift and carry the patient for any significant distance or down a flight of stairs. Make another attempt to lift and carry the patient after you have decreased the amount of proportional weight you will be carrying by changing your position on the device or the position of the others on the team, or after you have obtained additional help.

Safety

Know your limits! Always call for assistance as soon as you realize the patient's weight exceeds your lifting capabilities.

Planning the Move

Move a patient in an orderly, planned, directed, and unhurried manner. This approach will protect you and the patient from further injury and reduce the risk of worsening the patient's condition when the patient is moved.

At a minimum, on most calls you will have to lift and carry the patient to the wheeled ambulance stretcher, move the stretcher and patient to the ambulance, load and unload the stretcher from the patient compartment, and move the patient from the ambulance to the ED bed. You will often have to include several additional steps to place the patient onto a backboard and/or carry the patient down a flight of stairs. You will also have to add a stop at the top of the stairway so everyone can reposition to carry the patient down the stairs. Repositioning usually requires lowering the backboard to the ground and lifting it again when all providers are in their proper places. If you are carrying the patient in a stair chair, the additional step occurs after you have descended the stairs and reached the stretcher. At that point, you will have to assist or lift the patient from the stair chair onto the stretcher.

Plan ahead and carefully select the methods that will involve the least lifting and carrying. Always consider whether there is an option that will cause less strain to you and the other providers.

In addition, it is the responsibility of every team member to share with the leader any issue that may result in injury to anyone involved in the move.

Safety

Follow these rules to keep yourself and your patient safe:

- Minimize the number of total body lifts you have to perform.
- Coordinate every lift in advance.
- Minimize the total amount of weight you have to lift.
- Never lift with your back.
- Do not carry what you can put on wheels.
- Ask for help any time.

The Diamond Carry

A patient on a backboard or stretcher can be lifted and carried by four providers in a **diamond carry**, with one provider at the head end of the device, one at the foot end, and one at each side of the patient's torso. Follow the steps in **SKILL DRILL 6-3** to perform the diamond carry.

If you must carry a patient through a narrow doorway or hallway using a diamond carry, modify

Skill Drill 6-3 Performing the Diamond Carry

Step 1

To best balance the weight, four providers should be positioned at each side and end while facing the patient. Providers grasp the backboard or stretcher with one hand adjacent to the distal edge of the patient's pelvis and the other midthorax. When the command is given, all four providers lift the device while facing toward the patient.

Step 2

The provider at each side grasps the backboard or stretcher with the head-end hand.

Step 3

The providers at each side turn toward the patient's feet. The provider at the foot end turns to face forward. All four providers face the same direction and walk forward when carrying the patient.

© Jones & Bartlett Learning - Steven Sulewski Photography.

your positions (**FIGURE 6-8A**). Simply stop and have all the providers turn until each is again facing in toward the patient. Then, take small, slow steps to move through the doorway. If the doorway is still too narrow for the AEMTs at the sides of the backboard to fit through, one provider may need

to let go of the backboard and move through the doorway first. The remaining three providers can carry the backboard but may need to alter their positions before the fourth provider lets go, to properly balance the weight among three providers (**FIGURE 6-8B**). The fourth provider then steadies

**A****B**

FIGURE 6-8 Options for moving a patient through a narrow doorway or hallway while performing the diamond carry. **A.** Stop and turn in to face the patient until you move through the passage. **B.** If the doorway or hallway is very narrow, a provider on one side may move to the foot end and out of the way, and then steady and guide the other providers through the passage.

© Jones & Bartlett Learning.

and guides the first AEMT as this person moves through the passage.

A patient on a backboard or stretcher should be carried feet first to place the lightest load on the provider at the patient's feet, who, to walk forward, must turn and grasp the handles while facing away from the device. Carrying the patient feet first allows a responsive patient to see in the direction of movement.

The One-Handed Carrying Technique

One method of lifting and carrying a patient on a backboard is the one-handed carrying technique. With this method, four or more providers each use one hand to support the backboard so they can face forward as they are walking. To perform the one-handed carrying technique, follow the steps in **SKILL DRILL 6-4**.

Pick up and carry the backboard with your back in the locked-in position. If you need to lean to either side to compensate for a weight imbalance, you have probably exceeded your weight limitation. If this occurs, you may need additional assistance or you may need to reevaluate the carry; otherwise you or others might be injured or drop the patient.

Emergency Moves

When there is a potential for danger, use an **emergency move** to move a patient before assessment and care are provided. The presence of fire, explosives, or hazardous materials and your inability to protect the patient from other hazards or gain access to others in a vehicle who need life-saving care are all situations in which you should use an emergency move.

The only other time you should use an emergency move is if you cannot properly assess the

Skill Drill 6-4 Performing the One-Handed Carry

Step 1

Before lifting the backboard, ensure at least two providers are positioned on each side of the backboard facing each other and using both hands.

Step 2

Lift the backboard to carrying height using correct lifting techniques, including a locked-in back.

Step 3

After you have lifted the backboard to a carrying height, you and your partners turn in the direction you will be walking and switch to using one hand.

© Jones & Bartlett Learning.

patient or provide immediate potentially critical emergency medical care (for example, a patient in cardiac arrest) because of the patient's location or position.

If you are alone and danger at the scene makes it necessary for you to use an emergency move, regardless of a patient's injuries, use a drag to pull the patient along the long axis of the body. This will

help to keep the spinal column in line as much as possible. When performing an emergency move, one of your primary concerns is the danger of aggravating an existing spinal injury. Remember, it is impossible to remove a patient quickly from a vehicle while providing as much protection to the spine as you would give by using an immobilization device. However, if you follow certain guidelines

during the move, you can usually move a patient from a life-threatening situation without causing further injury to the patient.

You can move patients on their back along the floor or ground by using one of the following methods.

- Pull on the patient's clothing in the neck and shoulder area (**FIGURE 6-9A**). If the shirt has buttons, the top two should be undone to prevent choking the patient.
- If possible, place the patient onto a blanket, coat, or other item that can be pulled (**FIGURE 6-9B**).
- Rotate the patient's arms so they are extended straight on the ground beyond the patient's head, grasp the wrists, and, with the arms elevated above the ground, drag the patient (**FIGURE 6-9C**).
- Place your arms under the patient's shoulders and through the armpits, and, while grasping the patient's arms, drag the patient backward (**FIGURE 6-9D**).

If you are alone and must remove an unresponsive patient from a vehicle, follow the steps in **SKILL DRILL 6-5**.

If the legs and feet do not clear the vehicle easily, slowly lower the patient until the patient is lying on their back next to the vehicle, clear the legs from the vehicle, and, as previously described, use a long-axis body drag to move the patient a safe distance from the vehicle.

Use one-person techniques to move a patient only if a potentially life-threatening danger exists and you are alone or, because of the pressing nature of the danger, your partner is moving a second patient simultaneously. Additional one person drags, carries, and lifts are shown in **FIGURE 6-10**.

Urgent Moves

An urgent move is necessary when a patient requires immediate life-saving care, yet is in an unsafe environment. For example, an urgent move may be necessary for moving a patient with an altered level of consciousness, inadequate ventilation, or shock (hypoperfusion) but the needed care cannot be rendered where the patient is currently located. An extreme weather condition may also make an urgent move necessary. In some cases, patients must be urgently moved from the location or position in which

A

B

C

D

FIGURE 6-9 Dragging methods. **A.** Emergency clothes drag. **B.** Blanket drag. **C.** Arm drag. **D.** Arm-to-arm drag.

Skill Drill 6-5 One-Person Technique for Removing an Unresponsive Patient From a Vehicle

Step 1

Move the patient's legs against the seat so they are clear of the gas and brake pedals. Rotate the patient so the patient's back is positioned facing the open vehicle door. Place your arms through the patient's armpits and support the patient's head against your body.

Step 2

Support the patient's weight while lowering the patient down into a supine position.

they are found. When you need to urgently move a patient who is sitting in a car or truck, use the rapid extrication technique.

Rapid Extrication Technique

The backboard, short backboard, and vest-type devices are known as spinal immobilization devices. You usually use an extrication-type vest or short backboard device to immobilize a seated patient with a suspected spinal injury before removing the patient from the vehicle. However, proper placement of either of these devices on the patient usually requires between 6 and 8 minutes, and in some cases even longer. By using the **rapid extrication technique** instead, the patient can be moved from sitting in the vehicle to lying supine on a backboard in 1 minute or less. **TABLE 6-2** describes the situations in which you should use the rapid extrication technique. See Chapter 40, *Vehicle Extrication*,

Special Rescue, and Hazardous Materials, for more information.

In such cases, the delay that occurs in applying immobilization devices is contraindicated. However, the manual support and immobilization that you provide when using the rapid extrication technique produce a greater risk of spine movement. You should use the rapid extrication technique only if extreme urgency exists.

The rapid extrication technique requires a team of three providers who are knowledgeable and practiced in the procedure. The first provider is usually positioned in the backseat and applies in-line support and stabilization of the patient's head and neck. At some point, either because the doorpost is in the way or because the provider cannot reach farther from the backseat, the first provider will be unable to follow the torso rotation. At that time, the third (or even a fourth) provider assumes temporary in-line support of the head and neck. The provider

FIGURE 6-10 One-person drags, carries, and lifts. **A.** Front cradle. **B.** Firefighter's drag. **C.** One-person walking assist. **D.** Firefighter's carry. **E.** Pack-strap carry.

TABLE 6-2 Situations in Which to Use the Rapid Extrication Technique
The vehicle or scene is unsafe.
Explosives or other hazardous materials are on the scene.
There is a fire or a danger of fire.
The patient cannot be assessed properly before being removed from the vehicle.
The patient needs immediate intervention that requires a supine position.
The patient has a life-threatening condition that requires rapid transport to the hospital.
The patient is hemodynamically unstable.
The patient blocks your access to another seriously injured patient.

© Jones & Bartlett Learning.

at the patient's head always calls the moves. The second provider supports the torso. Because the second provider lifts and turns the patient's torso, the provider must be physically capable of moving

the patient. The third provider moves and supports the patient's legs. Take the steps shown in **SKILL DRILL 6-6** when using the rapid extrication technique.

Skill Drill 6-6 Performing the Rapid Extrication Technique

Step 1

The first provider applies manual in-line support of the patient's head and cervical spine from behind the patient, usually from the backseat. Support may be applied from the side, if necessary, by reaching through the driver's side doorway.

Step 2

The provider holding in-line stabilization gives commands, applies a cervical collar, and performs the primary survey from the driver's side doorway. If the first provider is also working from that doorway, the second provider should stand closer to the door hinges toward the front of the vehicle.

Step 3

The second provider provides continuous support of the patient's torso until the patient is supine on the backboard. The third provider works from the front passenger's seat and frees the patient's legs from the gas and brake pedals and moves the legs together, without moving the pelvis or spine. After the third provider moves the legs together, the legs should be moved as a unit.

Step 4

The second provider and the third provider rotate the patient as a unit in three or four short, quick "eighth turns" until the patient's back is facing out the driver's door and the legs are on the front passenger's seat. The first provider directs each quick turn by saying, "Ready, turn" or "Ready, move." Make hand position changes between moves. The first provider (relieved by the fourth provider or a bystander as needed) supports the patient's head and neck during rotation (and later steps).

(continues)

Skill Drill 6-6 Performing the Rapid Extrication Technique (*continued*)

Step 5

Once the patient has been rotated fully, place the backboard on the seat against the patient's buttocks. The second provider and the third provider lower the patient onto the board while supporting the head and torso to maintain neutral alignment. The first provider holds the backboard until the patient is secured. (Use of a backboard versus an alternative device to maintain spinal motion restriction may depend on local protocols.)

Step 6

The third provider moves across the front seat to be in position at the patient's hips. The backboard should be immediately in front of the third provider. The fourth provider maintains manual in-line support of the head and now takes over giving the commands. If a fourth provider is not present, direct a volunteer to assist you. The second provider maintains the direction of the extrication and stands with back to the door, facing the rear of the vehicle. The second provider grasps the patient's shoulders or armpits. On command, the second provider and third provider slide the patient along the backboard in 8- to 12-inch (20- to 30-cm) moves, repeating this slide until the patient's hips are firmly on the backboard.

Step 7

The third provider exits the vehicle and moves to the opposite side of the backboard opposite the second provider. On command, they continue to slide the patient along the backboard in 8- to 12-inch (20- to 30-cm) slides until the patient is placed fully on the backboard.

Step 8

The first (or fourth) provider continues to stabilize the patient's head and neck while the second provider and the third provider carry the patient away from the vehicle and onto the prepared stretcher.

In some cases, you can rest the head end of the backboard on the stretcher while the patient is moved onto the backboard. In other cases, you will not be able to do this. Once the backboard and patient have been placed on the stretcher, you should begin life-saving treatment immediately. If you used the rapid extrication technique because the scene was dangerous, you and your team should immediately move the stretcher a safe distance away from the vehicle before you assess or treat the patient.

Words of Wisdom

The person holding the cervical spine always calls the moves.

The steps of the rapid extrication technique must be considered a general procedure to be adapted as needed. For example, two-door vehicles differ from four-door models. Larger vehicles differ from smaller compact models, pickup trucks, and full-size sedans and four-wheel-drive vehicles. You will handle a large, heavy adult differently from a small adult or child. Every situation will be

different—a different vehicle, a different patient, and a different crew. Your resourcefulness and ability to adapt are necessary elements to successfully perform the rapid extrication technique.

Nonurgent Moves

When the scene is stable and the patient is in stable condition, carefully plan how to move the patient. If your patient move is rushed or not well planned, it may result in discomfort or injury to the patient, you, and your team. Before you attempt any move, the team leader must ensure there are enough personnel, identify and remove any obstacles, ensure the proper equipment is available, and clearly identify and discuss the procedure and path to be followed. In addition, remember, it is every team member’s responsibility to share with the leader any issue that may result in injury to anyone involved in the move.

In nonurgent situations, you and your team may choose one of several methods for lifting and carrying a patient. Three general methods are presented here, which may serve as a basis for your plan. Adapt these procedures to meet your needs on a case-by-case basis.

YOU

are the Provider

Part 3

As you form your plan for moving the patient, your partner obtains vital signs and the engine crew positions the bariatric stretcher. You tell the patient and your crew that the safest way to get him onto the stretcher is to roll him onto his side and hold him in position long enough to position a draw sheet underneath him. He reminds you to be careful with his sore back and bottom. After everyone voices understanding of the plan, you transfer the patient onto the draw sheet and move to the stretcher, where he is secured for transport.

Recording Time: 8 Minutes

Respirations	18 breaths/min; clear
Pulse	102 beats/min
Skin	Warm and dry
Blood pressure	146/88 mm Hg
Oxygen saturation (SpO ₂)	97% on room air
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

6. Why is it important to have only one person issuing commands when moving patients?

7. What are some advantages and disadvantages of a hydraulic stretcher?

Direct Ground Lift

The **direct ground lift** is used for patients with no suspected spinal injury who are found lying supine on the ground. Use this lift technique when you have to lift and carry the patient some distance to be placed on the stretcher. If you find the patient

semiprone or lying on the side, roll the patient onto the back. Ideally, the direct ground lift should be performed by three providers; however, it can be done with only two. To perform the direct ground lift, follow the steps in **SKILL DRILL 6-7**. Reverse the steps to lower the patient onto the stretcher.

Skill Drill 6-7 The Direct Ground Lift

Step 1

Line up on one side of the patient, with the first provider at the head, the second provider at the waist, and the third provider at the patient's knees. All providers kneel on one knee, preferably the same knee. Place the patient's arms on the chest, if possible. The first provider places one arm under the patient's neck and shoulders and cradles the patient's head. The first provider then places the other arm under the patient's lower back. The second provider places one hand under the patient's waist, and the other under the knees. The third provider places one arm under the patient's knees and the other under the ankles.

Step 2

On command, the providers lift up the patient to knee level as each provider rests an arm on their knee.

Step 3

Together and on command, each provider rolls the patient in toward their chest. Again on command, providers stand and carry the patient to the stretcher.

Extremity Lift

The **extremity lift** may also be used for patients with no suspected extremity or spinal injuries who are supine or in a sitting position on the ground. The extremity lift may be especially helpful when the patient is in a very narrow space or there is not enough room for the patient and a team of AEMTs to stand side by side.

Communication is the key to success with this lift. You and your partner must coordinate your movements through direct verbal

commands. Perform the extremity lift as seen in **SKILL DRILL 6-8**.

You are less likely to injure yourself if you bend at the hips and knees and use your legs for lifting. However, this lift and carry method increases the pressure on the patient's chest, so the patient may be uncomfortable in this position.

Transfer Moves

There are several ways to transfer the patient from a bed onto the stretcher.

Skill Drill 6-8 Extremity Lift

Step 1

Kneel behind the patient's head as your partner kneels at the patient's feet. The patient's hands should be crossed over the chest. Place one hand under each of the patient's armpits. Grasp the patient's wrists or forearms and pull the upper torso until the patient is in a sitting position.

Step 2

Your partner moves to a position between the patient's legs, faces the same direction as the patient, and slips their hands under the patient's knees.

Step 3

Rise to a crouching position. As you give the command, stand fully upright and move the patient to the stretcher.

Direct Carry

Transfer a supine patient from a bed to the stretcher using the **direct carry method** (**SKILL DRILL 6-9**).

Draw Sheet Method

To move the patient from a bed onto a stretcher, use the **draw sheet method**. Follow the steps in **SKILL DRILL 6-10**.

To avoid the strain of unnecessary lifting and carrying, you should use the draw sheet method to move the patient whenever possible. This method is not only easier on providers, but also easier on the patient. For example, if you try to help a heavy person to their feet, you could injure your shoulder or bruise the patient. In older patients, you could cause a skin tear because their skin is more fragile. The draw sheet method is less likely to cause these problems.

Skill Drill 6-9 Direct Carry

Step 1

Position the stretcher parallel to the bed. Secure the stretcher to prevent movement. Position yourself at the head end of the bed facing toward the patient. Your partner positions himself or herself between the bed and the stretcher and faces you and the patient. Place your arms under the patient's armpits. Your partner positions their hands under the patient's knees.

Step 2

Slowly and smoothly lift the patient in a smooth, coordinated fashion.

Step 3

Slowly carry the patient from the bed to the stretcher.

Step 4

Gently lower the patient onto the stretcher and secure with straps.

Skill Drill 6-10 Draw Sheet Method

Step 1

Loosen the bottom sheet under the patient, or log roll the patient onto a blanket.

Step 2

Place the stretcher next to the bed; ensure it is at the same height as, or slightly lower than, the bed. Hold or secure the stretcher to keep it from moving. Reach across the stretcher and grasp the sheet or blanket firmly at the patient's head, chest, hips, and knees.

Step 3

Gently slide the patient onto the stretcher.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Other Carries

Other carries are performed in the following manner:

- Place a backboard next to the patient, and, after using a log roll or slide to move the patient onto the backboard, secure the patient and lift and carry the backboard to the nearby prepared stretcher.
- Insert the halves of a scoop stretcher under each side of the patient, and fasten the two sides together. Lift and carry the patient to the nearby prepared stretcher. (Note: You can also log roll a patient onto a scoop stretcher that is already locked together.)
- Assist an able patient to the edge of the bed. Place the patient's legs over the side and help the patient to sit up. Move the stretcher so its foot end touches the bed near the patient. Help the patient to stand and rotate so they can sit down on the center of the stretcher. Lift the patient's legs, and rotate them onto the stretcher while your partner lowers the patient's torso onto the stretcher.

If a patient is able, you should always assist the patient to the stretcher to avoid the strain of unnecessary lifting and carrying.

Follow the steps in **SKILL DRILL 6-11** to use a scoop stretcher.

Skill Drill 6-11 Using a Scoop Stretcher

Step 1

With the scoop stretcher separated, measure the length of the scoop and adjust to the proper length.

Step 2

Position the stretcher, one side at a time. Slightly lift the patient's side by pulling on the far hip and upper arm, while your partner slides the stretcher into place.

Step 3

Lock the stretcher ends together by engaging its locking mechanisms one at a time and continue to slightly lift the patient as needed to avoid pinching.

Step 4

Secure the patient to the scoop stretcher, and transfer it to the stretcher.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Use one of the following methods to move a patient from the ground or the floor onto the stretcher:

- Lift and carry the patient to the nearby prepared stretcher using a direct ground lift.
- Use a log roll or long-axis drag to place the patient onto a backboard, and then lift and carry

the backboard to the stretcher. Place both the backboard and the patient onto the stretcher.

- Use a scoop stretcher.
- Log roll the patient onto a blanket.

Follow the steps in **SKILL DRILL 6-12** to lift a patient from the ground using a blanket.

Skill Drill 6-12 Lifting a Patient From the Ground

Step 1

Log roll the patient onto a blanket.

© Jones & Bartlett Learning

Step 2

Lift the patient using the blanket, and carry the patient to the nearby stretcher.

If the patient is sitting in a chair and cannot assist you, transfer the patient from the chair to a stair chair **SKILL DRILL 6-13**.

Geriatrics

Many patients transported by EMS are geriatric patients. For many older patients, the fear of illness and disability is ever present, and an emergency trip to the hospital can be a terrifying and disorienting experience. In addition, there are physiologic changes that occur with aging that require special attention on your part as an AEMT.

- **Skeletal changes.** Brittle bones (osteoporosis), rigidity, and spinal curvatures (kyphosis and scoliosis) (**FIGURE 6-11**) present special challenges in packaging and moving older patients. Many patients cannot lie supine on a

backboard or scoop stretcher without causing additional injury, such as fractures, pressure sores, and skin breakdown. Special care and creativity must be taken in immobilizing patients with such conditions. For example, a patient with spinal curvature may have to be placed on their side and immobilized in place with towel and blanket rolls to prevent exacerbating their injuries. Consult your local protocols and medical director about alternative ways of immobilizing the patient, and be familiar with effective methods for padding voids.

- **Skin changes.** Geriatric patients have delicate skin and are prone to significant skin tears and bruising during even the simplest moves. Protect their elbows when carrying or moving through hallways.
- **Fear.** A sympathetic and compassionate approach can go a long way in allaying the natural fears many older patients experience when interacting with caregivers. Slow down, explain, and anticipate: these actions can help you gain an older patient's cooperation and take some of the anxiety out of the process of packaging and transportation. Imagine how frightening being strapped to a stretcher and carried down a flight of stairs can be to a person who lives in constant fear of falls and broken bones.

Special Populations

Geriatric patients often fear the loss of their independence. What constitutes a minor injury for the average individual can be debilitating for an older person. Unless there is a true emergency, take the time to talk to geriatric patients, and reassure them often.

Skill Drill 6-13 Moving a Patient From a Chair to a Stair Chair

Step 1

Remove any removable side pieces on the chair or move the side pieces to a position to minimize interference. Slide your arms through the patient's armpits, and grasp the patient's crossed forearms. Your partner grasps the patient's legs at the knees.

© Jones & Bartlett Learning.

Step 2

Gently lift the patient into the locked stair chair.

A

B

FIGURE 6-11 Skeletal changes. **A.** Kyphosis. **B.** Scoliosis.

A: © Dr. P. Marazzi/Science Source; **B:** © ZUMA Press Inc/Alamy Stock Photo.

Special Populations

Cover the patient with a blanket to protect privacy and keep the patient warm. Remember to pad around the patient for comfort, especially if the patient must be immobilized on a backboard.

Words of Wisdom

Whenever possible, use a draw sheet to move geriatric or bariatric patients rather than lifting them by their arms. Geriatric patients have thin skin that may bruise or tear easily, and the sheer weight of a bariatric patient exerts a tremendous amount of pressure on the patient's extremities. Pulling on the arms of these patients may result in pain, dislocation, or skin tears.

Bariatrics

From 2017 through 2018, the prevalence of obesity in adults in the United States was 42.4%, according to the US Centers for Disease Control and Prevention.¹ The incidence of obesity is higher among adults aged 40 to 59 years (44.8%) than among adults aged 20 to 39 years (40%) or adults aged 60 years or older (42.8%). The numbers among children are also alarming; approximately 18.5% of all children aged 2 to 19 years in the United States are classified as obese.² Obesity has reached epidemic proportions in the United States, and many programs are now aimed at teaching people from a young age the importance of exercise and a healthy diet.

Obesity has become such a significant issue that a new field of medicine has emerged to provide specialty care for obese patients. **Bariatrics** is the branch of medicine concerned with the management (prevention or control) of obesity and allied diseases. It comes from the Greek words *baros*, weight, and *iatreia*, medical treatment. Because there is a direct correlation between the degree of

obesity and the frequency and severity of health problems, the larger the patient, the more likely the patient is to need emergency medical treatment and transportation. This problem is taking an increasing toll on the health and functioning of AEMTs because back injuries account for the highest number of missed days of work and for temporary and permanent disability.

Although equipment manufacturers are producing equipment with ever higher capacities, this does not address the danger to the users of that equipment. European ambulance manufacturers regularly install mechanical lifts on their units, but these are not as common in the United States.

Patient-Moving Equipment

The Wheeled Ambulance Stretcher

The **wheeled ambulance stretcher** (also called an ambulance stretcher, gurney, cot, litter, or simply “the stretcher”) can be rolled along the ground and

YOU are the Provider

Part 4

After you ensure your patient is properly secured and in a position of comfort, you wheel him out to your awaiting ambulance. As you arrive at the rear of the ambulance, you instruct your partner to take one corner of the stretcher, while you take the corner with the controls. On the count of three, you take pressure off the wheels, activate the controls to raise the undercarriage, and secure the patient into the back of the ambulance. You thank the engine crew for their assistance and inform your partner that this patient requires a smooth trip to the local ED. While en route, you obtain another set of vital signs and perform a more detailed examination. The patient explains he is being admitted to the hospital for treatment of his decubitus ulcers. Other than the pain, he has no other complaints. Once you arrive at the ED, you and your partner use the same process to take the patient out of the ambulance and safely move him to his room. You ask for additional assistance in moving the patient to his bed, and once he is positioned comfortably, you give your report to the nurse and return to service.

Recording Time: 52 Minutes

Respirations	18 breaths/min; clear

8. What steps should you take to safely roll the stretcher into the hospital?
9. How should this patient be moved onto the hospital bed?

FIGURE 6-12 The wheeled ambulance stretcher is specially designed to roll along the ground.

© Jones & Bartlett Learning.

weighs between 40 and 145 pounds (18 and 66 kg), depending on its design and features (**FIGURE 6-12**). Because its weight must be added to that of the patient's, it is generally not taken up or down stairs or to other locations where the patient must be carried rather than rolled for any significant distance. When the patient is upstairs, take the wheeled ambulance stretcher to the ground floor landing and prepare it for the patient. Then, take a wheeled stair chair, scoop stretcher, or backboard upstairs. These devices are considerably lighter than a wheeled stretcher and may be used to carry the patient to the waiting stretcher.

Follow the manufacturer's directions for maintenance, inspection, weight limitations, repair, and upkeep for any device that you use as patient-handling equipment.

Stretchers are available in a many models, which may include different features. Before going on a call, familiarize yourself with all the specific features of the stretcher that your ambulance carries. Know the location of the controls that adjust and lock each feature and how each feature works.

The stretcher has a specific head end and foot end. The stretcher has a strong horizontal rectangular tubular metal main frame to which all its other parts are attached. The stretcher should be pulled, pushed, and lifted only by its main frame or

handles, which are attached to the main frame specifically for this purpose.

On most models, a second tubular frame made up of three sections is attached within or above the main frame. A metal plate is fastened to each of the three sections between its sides. This plate serves as the platform on which the stretcher mattress and patient are supported. The head section runs from the head end of the stretcher to near the center of the stretcher, where the patient's hips will be. Hinges at the area where the hips will be allow the head end to be elevated and the patient's back to be positioned at any desired angle from flat to fully upright. The head end of the stretcher is designed to be elevated or moved down only when a tilt control is purposely released. At all other times, the back will remain locked at the position in which it was placed. The frame and plates that lie from the hips to the foot end of the stretcher are divided into two hinged sections. These sections may be connected so the foot end can be drawn in toward the knees, causing the frame and plates to hinge upward under the patient's knees to elevate them as desired. This feature is not found in all models.

A retractable guardrail is attached along the central portion of the main frame of the stretcher at each side and is lowered out of the way when a patient is being loaded onto the stretcher. Once the patient has been properly placed on the stretcher, the handle is drawn up and locked in an elevated position perpendicular to the surface of the stretcher. The patient cannot roll off either side of the stretcher even if a securing strap becomes released. The guardrail at each side can be lowered only if its locking handle is released.

The underside of the main frame of the stretcher is supported on a folding undercarriage that has a smaller horizontal rectangular frame and four large rubber casters at its bottom end. The folding undercarriage is designed to allow the stretcher to be adjusted to any height from about 12 inches (30 cm) above the ground, which is the desired height when the stretcher is secured in the ambulance, to 32 to 36 inches (81 to 91 cm) above the ground, which is the desired height when the stretcher is being rolled. Because you are able to lock the stretcher at any height between its lowest height and its fully extended height, it can be locked at the same height as any bed or examining table to allow the patient to be slid from one to the other. This permits you

to transfer the patient without the need for any additional lifting. The controls for folding the undercarriage allow the stretcher to remain locked at its present height when the controls are not being activated. As an additional safety feature on most stretchers, the main frame must be lifted slightly so the undercarriage becomes unweighted before it will fold, even if the control is pulled. Therefore, if the handle is accidentally pulled, the elevated stretcher will not suddenly drop. Controls for elevating and lowering most stretchers are located at the foot end and at one or both sides. You and your partner must use the proper lifting mechanics to lift the wheeled ambulance stretcher.

The mattress on a stretcher must be fluid resistant so it does not absorb any type of potentially infectious material, including water, blood, or other body fluid.

Most patients are placed directly on the stretcher. However, patients with possible spinal injuries or multiple systems trauma are often placed and secured onto a backboard before placing them on the stretcher. Patients who may need cardiopulmonary resuscitation or must be carried down (or up) a flight of stairs while supine should also be placed on a backboard. The backboard and patient are then secured onto the stretcher.

Always secure patients with the straps on the stretcher. In the event of a crash while en route to the hospital, the straps help prevent further injury to the patient.

Words of Wisdom

Ensure a thorough patient care report by including details of how you moved the patient. For example, "Moved patient to stretcher with draw sheet method."

Bariatric Stretchers

Because of their large girth, bariatric patients may not fit comfortably on the standard wheeled stretcher. As a result, a specialized type of wheeled stretcher has been developed, called the bariatric stretcher (**FIGURE 6-13**). This type of stretcher is similar in design to the common wheeled stretcher; however, it has several differences. Bariatric stretchers typically have a wider patient surface area to allow for increased comfort and increased dignity for

FIGURE 6-13 A bariatric stretcher.

Courtesy of Stryker Medical, a division of Stryker Corporation.

the patient. Bariatric stretchers also have a wider wheelbase, allowing for increased stability when rolling the patient over uneven terrain. Bariatric stretchers are also sometimes equipped with optional features such as a tow package, which allows an ambulance-mounted winch to assist in loading the patient into the ambulance, decreasing the potential for AEMTs to sustain back injuries. Another optional feature is telescoping side lift handles, which allow for increased leverage when lifting with multiple providers. However, the most important feature of the bariatric stretcher is the increased weight-lifting capacity. Typical wheeled ambulance stretchers, depending on manufacturer ratings, are rated to a maximum weight of 650 pounds (295 kg). Bariatric stretchers are usually rated between 850 and 900 pounds (386 and 408 kg).

Pneumatic and Electronic Powered Wheeled Stretchers

To decrease the potential for back injuries to EMS providers, manufacturers have developed pneumatic and electronic stretchers. Similar in appearance to conventional wheeled stretchers, electronic stretchers are battery operated and have electronic controls to facilitate raising and lowering of the undercarriage at the touch of a button (**FIGURE 6-14**). A drawback to the powered wheeled stretcher is that by adding the electronic controls, as well as the associated equipment, the weight of the stretcher is increased, typically by 75 to 100 pounds (34 to 45 kg). Combined with the weight of the patient on the loaded stretcher, this creates a potential hazard when transporting the patient over uneven terrain or down one or two steps in the front of a residence.

FIGURE 6-14 An electronic stretcher.

Courtesy of Stryker Medical, a division of Stryker Corporation.

Loading the Wheeled Stretcher Into an Ambulance

Whenever a patient has been placed onto the stretcher, one AEMT must hold the main frame to ensure it does not roll. When the stretcher is elevated, the main frame and the patient extend considerably beyond the wheels at both the head end and foot end of the stretcher. Therefore, whenever a patient is on an elevated stretcher, ensure it is held firmly between two hands at all times so even if the patient moves, the stretcher cannot tip (**FIGURE 6-15**).

If the loaded stretcher must be carried down a short flight of stairs, first, retract the undercarriage; however, this is not necessary when the stretcher must be lifted over a curb, a single step, or an obstacle of a similar height (**FIGURE 6-16**). Remember, if the patient must be carried up or down a full flight or several flights of stairs, prepare the stretcher and leave it on the ground floor at the bottom (or top) of the stairs. Use a backboard or stair chair to carry the patient up or down the stairs to the waiting stretcher.

Follow the steps shown in **SKILL DRILL 6-14** to load the stretcher into an ambulance.

The clamps will hold the stretcher in place until they are released at the hospital. You can control and release the clamps with a single handle that is positioned so that you can activate it when standing on the ground at the open back doors of the ambulance when the stretcher is to be unloaded. The stretcher is designed to be rolled on regular flat surfaces. If the patient must be moved over a lawn or other irregular surface, lift and carry the stretcher over the terrain.

FIGURE 6-15 Always hold the main frame of the stretcher when it is elevated so that even when the patient moves, the stretcher does not tip.

© Jones & Bartlett Learning - Steven Sulewski Photography.

FIGURE 6-16 You do not need to retract the undercarriage of the stretcher when lifting it over a curb, a single step, or an obstacle of similar height.

© Jones & Bartlett Learning - Steven Sulewski Photography.

An intravenous (IV) pole is attached to many stretchers. The IV pole can be unfolded or extended above the main frame to hold an IV bag above the patient while you move the stretcher to the ambulance. Some wheeled ambulance stretchers even include a carrier to hold an electrocardiographic monitor or automated external defibrillator and portable oxygen unit. If the model you use does not include these features, secure the portable oxygen unit and cardiac monitor and automated external defibrillator to the top surface of the stretcher mattress at the patient's legs; however, remember, when you attempt to lift the stretcher that these items will add more weight.

Skill Drill 6-14 Loading a Stretcher Into an Ambulance

Step 1

Tilt the head end of the stretcher upward, and place it into the patient compartment with the wheels on the floor. Ensure the safety bar under the head of the stretcher catches on the hook prior to lifting the stretcher.

Step 2

With the patient's weight supported by the two head-end wheels and the provider at the foot end of the stretcher, move to the side of the main frame and release the undercarriage lock to lift the undercarriage up to its fully retracted position.

Step 3

Roll the stretcher the rest of the way into the back of the ambulance, where it will rest on all six wheels.

© Jones & Bartlett Learning - Steven Sulewski Photography.

Step 4

Secure the stretcher to the clamps mounted in the ambulance.

The extra wheels below the head end of the main frame of the stretcher are not featured on some older or less-expensive wheeled ambulance stretchers. These stretchers are not self-loading. When you reach the back of the ambulance with such a stretcher, you must lower it until the undercarriage

is in its lowest retracted position and then, with you and your partner at each side of the stretcher, lift it to the height of the floor of the ambulance and roll it into the track that locks it into place. **TABLE 6-3** shows the guidelines that you must follow to load the stretcher into the ambulance.

TABLE 6-3 Guidelines for Loading the Stretcher Into the Ambulance

Make sure there is sufficient lifting power.

Follow the manufacturer's directions for safe and proper use of the stretcher.

Make sure that all stretchers and patients are fully secured before the ambulance is moved.

© Jones & Bartlett Learning.

Portable/Folding Stretchers

A **portable stretcher** is a stretcher with a strong, rectangular, tubular metal frame and rigid fabric stretched across it (**FIGURE 6-17**). Portable stretchers do not have a second multipositioning frame or adjustable undercarriage. Some models have two wheels that fold down about 4 inches (10 cm) underneath the foot end of the frame and legs of a similar length that fold down from the head end at each side. The wheels make it easier to move the loaded stretcher. The legs should not be used as handles.

Some portable stretchers can be folded in half across the center of each side so the stretcher is only one-half its usual length during storage. Many ambulances carry a portable stretcher to use if a patient is in an area that is difficult to reach with a wheeled ambulance stretcher or a second patient must be transported on the squad bench of the ambulance.

A portable stretcher weighs much less than a wheeled stretcher and does not have a bulky undercarriage. However, because most models do not have wheels, you and your team must support all of the patient's weight and any equipment along with the weight of the stretcher.

Flexible Stretchers

Several types of flexible stretchers, such as the Sked, Reeves, and Navy stretchers, are available and can be rolled up across either the stretcher's width or, in the case of the Sked, its length, so the stretcher becomes a smaller tubular package for storage and carrying (**FIGURE 6-18**). This is an important consideration when you must carry the equipment a considerable distance from the nearest place that the ambulance can be located. A **flexible stretcher**

**FIGURE 6-17** A portable stretcher.

© Dorling Kindersley Ltd./Alamy Stock Photo.

**FIGURE 6-18** A flexible stretcher.

© Jones & Bartlett Learning. Photographed by Glen E. Ellman.

forms a rigid stretcher that conforms around the patient's sides and does not extend beyond them. When these stretchers are extended, they are particularly useful when you must remove a patient from or through a confined space. Certain flexible stretchers can also be used if the patient must be belayed or rappelled by ropes.

The flexible stretcher is the most uncomfortable of all the various devices, but it provides excellent support. When the stretcher is wrapped around the patient and the straps are secured, the patient is completely immobilized. The stretcher can then be lowered by rope or slid down a flight of stairs by resting it on the front edge of each step.

Backboards

When a patient is unresponsive, in cardiac arrest, must be moved in a supine position, or must be immobilized, secure the patient onto a backboard. A **backboard** is a device used to carry patients and to immobilize supine patients with suspected hip, pelvic, spinal, and lower extremity injuries or other multiple trauma (**FIGURE 6-19**). Backboards can also be used to move patients out of awkward places and to provide a rigid surface

FIGURE 6-19 A backboard is used to transfer patients who must be moved in a supine or immobilized position.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

for patients in cardiac arrest. They are also called long backboards, spine boards, trauma boards, or longboards.

Backboards are long, flat, rectangular boards made of rigid material. They are 6 to 7 feet long (approximately 2 m) and are commonly used for patients who are found lying down. Parallel to the sides and ends of the backboard are several long holes that are approximately 0.5 to 1 inch (1 to 3 cm) from the outer edge. These holes form handles and handholds so the board can be easily grasped, lifted, and carried. The handles and adjacent holes also allow straps to be used to secure and immobilize the patient to the backboard to be secured to each side and end of the backboard at any needed location.

Modern backboards are typically made of plastic. For many years, backboards were made of thick marine plywood whose surface was sealed with polyurethane or another marine varnish. Wooden backboards are still used in some places. If you use wooden backboards, follow infection control procedures before you reuse the backboards. Where wooden backboards are no longer used, they have generally been stored so they will be available in the event of a mass-casualty incident. Newer backboards are made of lighter plastic materials that will not absorb blood or other infectious substances.

Use a short backboard to immobilize the torso, head, and neck of a seated patient with a suspected spinal injury until you can immobilize the patient on a long backboard. Short backboards are 3 to 4 feet long (approximately 1 m). The original short wooden backboard has generally been replaced with a vest-type device that is specifically designed

FIGURE 6-20 The Kendrick Extrication Device is a vest-type immobilization device.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

to immobilize the patient until the patient is moved from a sitting position to supine on a backboard (**FIGURE 6-20**). The vest-type devices are easier to use than the wooden short backboard.

Words of Wisdom

The standard use of backboards is a very controversial subject. Many services have moved away from immobilizing every trauma patient and instead are using assessment-based guidelines to determine need. For more information on the use of backboards, refer to Chapter 30, *Head and Spine Injuries*.

Vacuum Mattresses

Another alternative to the backboard, especially for immobilizing geriatric and pediatric patients, is the vacuum mattress. With this device, the patient is placed on the mattress and the air is removed from the device, allowing it to mold around the patient. It fits snugly to the curvatures and contours of the body and limits pressure point tenderness. As the mattress molds to the body, it provides a high degree of immobilization and comfort. It also provides thermal insulation, thereby reducing the risk of hypothermia. Padding may be used for tender areas, but is not required for most patients. Vacuum mattresses result in dramatic improvement in patient comfort relative to backboards with an equivalent or even better degree of spinal motion restriction.

It is imperative to maintain spinal motion restriction while placing the patient on the device and

to secure the patient properly once placed on the mattress. The vacuum mattress cannot be used on patients weighing 350 pounds (159 kg) or more. See Chapter 30, *Head and Spine Injuries*, for more information about the vacuum mattress.

Basket Stretchers

Use a rigid **basket stretcher**, often called a Stokes litter or Stokes basket, to carry a patient across uneven terrain from a remote location that is inaccessible by ambulance or other vehicle (**FIGURE 6-21**). If you suspect the patient has a spinal injury, first immobilize the patient on a backboard and then place the backboard into the basket stretcher. Once you have reached the ambulance and wheeled ambulance stretcher, remove the patient secured to the backboard from the basket stretcher and place the patient on the stretcher.

Basket stretchers are made of plastic with an aluminum frame or have a full steel frame that is connected by a woven wire mesh. The wire basket is very uncomfortable for the patient unless the wire is padded. Either type can be used to carry a patient across fields, rough terrain, or trails or on a toboggan, boat, or all-terrain vehicle. Basket stretchers surround and support the patient, yet their design allows water to drain through holes in the bottom. Basket stretchers are also used for technical rope rescues and some water rescues. Not all basket stretchers are rated or appropriate for each of these specialized rescue uses. The types of basket

FIGURE 6-21 A basket stretcher.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

stretchers that are acceptable for specialized rescue must be determined by people with additional special training.

Scoop Stretchers

The **scoop stretcher**, also referred to as an orthopaedic stretcher, is designed to be split into two or four sections (**FIGURE 6-22**). These sections are fitted around a patient who is lying on the ground or another relatively flat surface. The parts are reconnected, and the patient is lifted and placed on a long backboard or stretcher.

A scoop stretcher is efficient; however, both sides of the patient must be accessible. You must pay special attention to the closure area beneath the patient so clothing, skin, and other objects are not trapped or pinched. Scoop stretchers are narrow, well-constructed, and compact and have excellent body support features but are not adequate when used alone for standard immobilization of a spinal injury. You and your team should practice often with a scoop stretcher so you are ready to use it with a patient.

Words of Wisdom

To use a stair chair, the patient must be alert and oriented and able to remain in an upright seated position. Otherwise, you must adopt another method for moving the patient.

Stair Chairs

A **stair chair** is a lightweight folding chair with a molded seat, adjustable safety straps, and fold-out handles at both the head end and foot end (**FIGURE 6-23**). Stair chairs serve as an adjunct for moving a responsive patient up or down stairs to

FIGURE 6-22 A scoop stretcher.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

FIGURE 6-23 A wheeled stair chair can be used to transfer a responsive patient up or down a flight of stairs.

© Jones & Bartlett Learning.

the ground floor, to the waiting wheeled ambulance stretcher. Use a stair chair if the patient's condition allows the patient to be placed in a sitting position.

Most models have rubber wheels in the back with casters in front so they can roll and make turns along the floor. Some have a specially designed track to facilitate movement down steps with little lifting required. Roll the stair chair on the floor until you reach the stairwell, then both providers carry it (rather than roll and bump it) up or down the stairs. Once you reach the ground floor, roll the stair chair to the waiting stretcher and assist or lift the patient onto the stretcher.

Ensure the wheeled ambulance stretcher is at the proper height, lower the side rails, turn down the cover sheet, and remove any equipment that you may have secured on the top.

Follow the steps shown in **SKILL DRILL 6-15** to use a stair chair.

As with other carries, always remember to keep your back in a locked-in position and to flex at the hips, not the waist. Bend at the knees and keep the

Skill Drill 6-15 Using a Stair Chair

Step 1

Secure the patient to the stair chair with straps. One provider should be positioned at the head end and one provider at the foot end. The provider at the head will coordinate lifts and movement. If a third provider is on scene, the third provider keeps their hand on the back of the second provider who is at the patient's feet. The third provider will open doors and provide guidance and support.

© Jones & Bartlett Learning.

Step 2

When you reach landings and other flat intervals in the move, lower the chair to the ground and roll the chair to the next position. When you reach the ground level where the stretcher awaits, roll the chair into position next to the stretcher in preparation for transferring the patient.

patient's weight and your arms as close to your body as possible. Twisting while carrying or moving a patient will increase your risk of injury. Avoid lifting and carrying the patient unnecessarily. A log roll or a body drag may aid you in moving your patient onto the backboard or the stretcher. Use one of these moves, if these techniques will not harm or jeopardize your patient's condition.

Moving a Patient on Stairs With a Backboard

Do not use a stair chair if a patient is unresponsive, in cardiac arrest, must be moved in a supine position, or must be immobilized; instead, secure the patient onto a backboard. Ensure the patient is anatomically secured to the device so the patient cannot slide significantly when the backboard is at an angle. Carry the patient on the backboard down the stairs to the prepared stretcher. More than one-half of a patient's weight is distributed to the head end of the backboard when moving on stairs, so ensure

the strongest provider is positioned at the head end. (Even with four or more providers carrying the patient, the strain on the provider at the head end will be increased when you must negotiate a narrow flight of stairs.) In carrying a patient up or down a flight of stairs, proportionally greater weight will also be distributed to the provider who carries the foot end when the device becomes angled because of the incline or decline. You should anticipate this and, in such cases, ensure the two strongest providers are positioned at the head and foot ends of the board. Because of the incline of the stairway, if one of the two strongest providers is considerably taller than the other, it will be easier if the shorter provider is at the head end and the taller provider is at the foot end. This minimizes bending while lifting and moving the patient. Once you reach the stretcher, place both the backboard and the patient on the stretcher; then secure both to the stretcher with additional straps.

To carry a patient on stairs on a backboard, follow the steps in **SKILL DRILL 6-16**.

Skill Drill 6-16 Carrying a Patient on Stairs

Step 1

Strap the patient securely. Ensure one strap is tight across the patient's upper torso, under the arms, and secured to the handles to prevent the patient from sliding.

© Jones & Bartlett Learning.

Step 2

When you carry the patient down stairs or an incline, ensure the backboard or stretcher is carried with the foot end first so the head end is elevated higher than the foot end.

Words of Wisdom

Make sure the stretcher is prepared prior to lifting the patient. Ensure the side rail is down, the stretcher is at a height that will not require you to lift the board any higher, the straps are unfastened and out of the way, and the head and foot ends are positioned appropriately to allow a smooth transition without having to rotate the stretcher or move around it.

Neonatal Isolettes

When you are requested to transport a neonatal patient from one hospital to another, the common wheeled ambulance stretcher will not suffice. To safely transport a neonatal patient, the patient must be placed inside an **isolette**, sometimes referred to as an incubator. The isolette keeps the neonatal patient warm with moistened air in a clean environment and helps to protect the infant from noise, drafts, infection, and excess handling. The specialized transport devices come in two forms: the isolette that is placed directly on top of the wheeled stretcher and secured with seat belts, and the freestanding isolette that is secured into the back of the ambulance, taking the place of the standard stretcher (**FIGURE 6-24**). Isolettes are often utilized by advanced practice personnel. Carefully follow their directions when assisting with the isolette.

FIGURE 6-24 Neonatal isolette.

© AndyL/E+/Getty images.

Decontamination

It is essential that you decontaminate your equipment after each use, for your safety, the safety of the crew using the equipment after you, and the safety of your patients. Decontamination prevents the spread of disease. Just as we expect a hospital bed to be disinfected after the last patient, your stretcher and other transport equipment must be disinfected too. Know and follow your local standard operating procedures for disinfecting equipment after each call.

Patient Positioning

While you are treating a patient, you must ensure the patient is properly positioned based on the chief complaint. Certain patient conditions, such as head injury, shock, spinal injury, pregnancy, and obese patients, call for special lifting and moving techniques. While a patient with a potential spinal injury should be fully immobilized, a patient with no suspected injury who reports chest pain or respiratory distress should be placed in a

Special Populations

Certain patient conditions, such as head injury, shock, spinal injury, and pregnancy, call for special lifting and moving techniques. Patients with chest pain or difficulty breathing should sit in a position of comfort, as long as they are not hypotensive. Those with suspected spinal injuries must be moved in a way that effectively restricts spinal motion such as a long backboard, a vacuum mattress or with careful maintenance of spinal alignment on a stretcher. Patients who are in shock should be packaged and moved in the position dictated by local protocol for shock. Pregnant patients who are hypotensive should be positioned and transported on their left sides. Move unresponsive patients with no suspected spinal injury into the recovery position by rolling them onto their side without twisting the body. Transport a patient who is nauseated or vomiting in a position of comfort, but be sure you are positioned appropriately to manage the airway. Obese patients should be positioned the same as other patients; however, pay particular attention to ensure you maintain their dignity.

position of comfort—typically a Fowler or semi-Fowler position—unless the patient is hypotensive. Patients who are in shock should be packaged and placed in a supine position. Patients in the third trimester of pregnancy should be positioned and transported on their left side if they are uncomfortable or hypotensive when supine. Place an unresponsive patient with no suspected spinal, hip, or pelvic injury into the recovery position by rolling the patient onto their side without twisting the body. Transport a patient who is nauseated or vomiting in a position of comfort, but ensure you are positioned appropriately to manage and maintain a patent airway. Obese patients should be positioned the same as other patients with similar conditions; however, pay particular attention to ensure you maintain their dignity.

Medical Restraints

Although not a common occurrence, there may be a time when you are called on to physically restrain a patient. After you evaluate the patient for correctable causes of combativeness, such as head injury, hypoxia, and hypoglycemia, the decision needs to be made as to whether to restrain your patient. There may be legal consequences for applying the restraints or failing to restrain a patient who should have been restrained. Contact law enforcement and consult local protocols before applying restraints; in some jurisdictions, medical control authorization is needed before an AEMT may apply restraints. See Chapter 24, *Psychiatric Emergencies*, for more detail about managing patients having psychiatric emergencies, including the use of restraints.

The decision to restrain a patient is not one you should take lightly; however, if the patient is posing a danger to you, your crew, himself or herself, or to bystanders, consider applying physical restraints. Before you restrain the patient, attempt to speak to the patient in a calm manner, but remain firm in your requests. If that does not work and the patient continues to be combative, all providers present should develop a plan as to who will do what, when it will happen, and how you will accomplish the restraint.

There should be a minimum of five providers present to assist in the restraint of a combative patient, one for each extremity and one for the head.

One AEMT should be established as the team leader, the one who will give commands. A plan to restrain the patient should be developed and agreed on by all providers. A patient who is caught off guard and is unsuspecting allows for a decreased likelihood of injury to the providers.

When you prepare to secure the patient on the stretcher, it is important to have the patient in the supine position. If the patient is placed in a prone position, a condition called positional asphyxia could develop. In the prone position, the increased weight on the patient's lungs and the patient's inability to fully expand the thoracic cavity could render the patient unable to breathe, creating a preventable, life-threatening emergency.

If a patient for whom use of medical restraints is indicated is in the supine position, some type of humane restraint should be applied to each extremity, such as triangular bandages; roller gauze; soft, commercially available disposable restraints; or leather restraints. Preferably the patient should be restrained onto a backboard, which allows for easy movement should the patient begin to vomit. However, if it is impractical or inadvisable to secure the patient to the backboard, then secure the patient to the stretcher. Regardless of whether the patient is secured to a backboard or the stretcher, one arm should be secured above the patient's head and one arm should be secured at the patient's side. This technique will not give the patient the leverage to break free from the restraints. After the upper extremities are secured, each leg should be secured as well. Ensure you will be able to quickly remove the restraints during transport if necessary. Patients should not be transported in handcuffs unless a police officer rides in the ambulance with you during transport.

After you apply the restraints, assess and continually reassess the patient's ABCDEs (airway, breathing, circulation, disability, and exposure), mental status, and distal circulation (pulse and motor and sensory function). Document your findings on the patient care report. Include what types of restraints were used and why.

Personnel Considerations

To minimize personnel injuries, before moving any patient, a complete plan needs to be developed and discussed among the team members. One question

Words of Wisdom

After you deliver the patient to the ED, you and your team must begin preparing for your next call. Review the positive points about the transport. Discuss changes that would improve the next run. Review and evaluate the process to identify the following:

- Procedures that need more practice
- Equipment that needs to be cleaned or serviced
- Skills that you need to review or acquire

Most important, a critical review helps you and your team to become more confident and better-skilled AEMTs.

to ask is: Am I physically strong enough to lift or move this patient? Many back injuries are the result of poor physical condition. As an AEMT, you will be required to assist in moving patients. Do your best to maintain a level of physical fitness. Other questions may include: Is there adequate room to get the proper stance to lift the patient? Do I need additional providers for lifting assistance? Evaluate the answers to these questions before you move your patient. Remember, injured providers cannot help anyone.

YOU are the Provider SUMMARY

1. What additional resources may be needed to move this patient?

When you attempt to move patients who weigh more than 250 pounds (113 kg), it is recommended you use at least four people to assist you in the move. Always know your limits and do not attempt to lift more than you are physically capable of lifting; otherwise, you may injure yourself, your partner, and the patient.

2. How will you move this patient from his bed to the stretcher?

Use the draw sheet method to move this patient from his bed to the EMS stretcher. Ensure the sheet is durable and all slack has been taken up prior to the move. The stretcher should be positioned next to the patient's bed with the mattress of the stretcher slightly lower than the mattress of the patient's bed. This will prevent the EMS mattress from rolling onto itself during the transition.

3. What are some potential complications when patients are moved improperly?

Your safety, as well as the safety of the other AEMTs and the patient, depends on using proper lifting techniques and having and maintaining a proper hold when lifting or carrying a patient. If you do not have proper hold of the stretcher or the patient in a body lift, you will not be able to bear a proper share of the weight, which may increase the chance you could suddenly lose your grasp with one or both hands. If you temporarily lose your grasp, the position and weight distribution of the stretcher changes

suddenly, and the other members of the team must quickly reach beyond a safe distance to avoid dropping the patient. As a result, sudden excessive force may be placed across each one's spine, causing lower back injury.

4. Should you use an emergency, urgent, or nonurgent move?

In this scenario, use a nonurgent move. When the scene is stable and the patient is in stable condition, carefully plan how to move the patient. If the move is rushed or not well planned, it may result in discomfort or injury to the patient, you, and your team. Before you attempt any move, the team leader must ensure there are enough personnel, identify and remove any obstacles, ensure the proper equipment is available, and clearly identify and discuss the procedure and path to be followed. In nonurgent situations, you and your team may choose one of several methods for lifting and carrying a patient.

5. What are some of the differences between a normal stretcher and a bariatric stretcher?

Bariatric stretchers typically have a wider patient surface area to allow for increased comfort and increased dignity for patients. Bariatric stretchers also have a wider wheelbase, allowing for increased stability when rolling the patient over uneven terrain. Bariatric stretchers are also sometimes equipped with optional features such as a tow package, which allows an ambulance-mounted winch to assist in loading the patient into the ambulance, decreasing the potential for back injuries. Another optional feature is telescoping side lift handles, which allow

YOU are the Provider **SUMMARY** *continued*

for increased leverage when lifting with multiple providers. However, the most important feature of the bariatric stretcher is the increased weight-lifting capacity. Typical wheeled ambulance stretchers, depending on manufacturer ratings, are rated to a maximum weight of 650 pounds (295 kg). Bariatric stretchers are usually rated to 850 to 900 pounds (386 to 408 kg).

6. Why is it important to have only one person issuing commands when moving patients?

To safely lift and carry a patient, you and your team must anticipate and understand every move, and each move must be executed in a coordinated manner. The team leader should indicate where each team member is to be located and rapidly describe the sequence of steps that will be performed to ensure team members know what is expected before they initiate any lifting. If you must lift and move the patient through several separate steps, the team leader should first give an abbreviated overview of the steps, followed by a more detailed explanation of each step just before it will occur. By having an identified team leader issuing commands, everyone involved in the move will know who is in charge and who will be issuing the commands.

7. What are some advantages and disadvantages of a hydraulic stretcher?

To decrease the potential for back injuries to EMS providers, manufacturers have developed pneumatic and electronic stretchers. Similar in appearance to conventional wheeled stretchers, electronic stretchers are battery operated and have electronic controls to facilitate raising and lowering the undercarriage at the touch of a button. A drawback to the powered wheeled stretcher is that by adding the electronic controls, as well as the associated equipment, the

weight of the stretcher is increased, typically by 75 to 100 pounds (34 to 45 kg). Combined with the weight of the patient on the loaded stretcher, this creates a potential hazard when transporting the patient over uneven terrain or down one to two steps in the front of a residence.

8. What steps should you take to safely roll the stretcher into the hospital?

When you are rolling the wheeled ambulance stretcher, make sure you elevate it. Pull the stretcher from the foot end. Make sure your arms are held close to your body, and avoid reaching significantly behind you or hyperextending your back. Your back should be locked, straight, and untwisted. While you are walking and pulling the stretcher, bend slightly forward at the hips. Keep the line of the pull through the center of your body by bending your knees.

9. How should this patient be moved onto the hospital bed?

In this scenario, the stretcher should be placed directly next to the hospital bed. The draw sheet that was used to move the patient initially should be used to move him to the hospital bed. Ensure the stretcher is at the same height as the bed and held firmly against its side. Then, you and another AEMT should kneel on the hospital bed and pull on the draw sheet smoothly and evenly to glide the patient in increments until he is properly centered on the bed. Request additional help to assist in lessening the strain on you and your partner. When you transfer the patient onto a narrow examining table, rather than kneel on the table, drag the patient while standing against the opposite side. A third person may need to take both sides of the head to safely move the patient. Some hospitals use a sliding board that helps to facilitate the move from bed to bed.

Narrative

EMS dispatched to above location for transport of a patient to the hospital for a direct admission. On arrival, patient found supine in bed, alert and oriented $\times 4$, ABCs intact; weight 325 lb (147 kg), per the patient. Chief complaint is pain from decubitus ulcers for which patient is being admitted. Additional lifting assistance requested and engine crew utilized to assist in moving patient via the draw sheet method from his bed onto a bariatric stretcher. Patient placed in a position of comfort, secured to stretcher, and loaded into the ambulance for transport. Nonemergency transport initiated. En route: Vitals as above. Detailed assessment is unremarkable. Patient was transported to Room 223 on the surgical floor where additional assistance was requested to move patient into bed. Patient moved without incident, report given to bedside nurse, and unit returned to service.

End of report

Prep Kit

Ready for Review

- The first key rule of lifting is to always keep your back in an upright position and lift without twisting or bending. You can lift and carry a substantial weight without injury as long as your back is in the proper upright position.
- The power lift is the safest and most powerful way to lift.
- The safety of you, your team, and the patient depend on the use of proper lifting techniques and maintaining a proper hold when lifting or carrying a patient.
- Pushing a stretcher is mechanically better than pulling.
- If you do not have a proper hold in a body lift, you will not be able to bear your share of the weight, and you may lose your grasp with one or both hands and possibly cause a lower back injury to one or more AEMTs.
- Use the power grip to get the maximum force from your hands whenever you are lifting a patient.
- Directions and commands are an important part of safe lifting and carrying. You and your team must anticipate and understand every move and execute it in a coordinated manner. The team leader is responsible for coordinating the moves.
- The same basic body mechanics apply for safe reaching and pulling as for lifting and carrying. Keep your back locked and straight, and avoid twisting. Do not hyperextend your back when reaching overhead.
- It is always best to move a patient on a device that can be rolled. However, if a wheeled device is not available, you must understand and follow certain guidelines for carrying a patient on a stretcher.
- When lifting a stretcher, ensure you and your team use correct lifting techniques. Ideally, members of the lifting team should be of similar height and strength.
- Use four providers whenever resources allow. Also, know how much you can comfortably and safely lift, and do not attempt to lift more than this weight. Rapidly summon additional help to lift and carry a weight that is greater than you are able to lift.
- If you must carry a loaded backboard or stretcher up or down stairs or other inclines, ensure the patient is secured tightly to the device to prevent sliding.
- Ensure the patient's head is elevated higher than the feet whenever possible.
- Whenever there is a potential for danger, use an emergency move to move a patient before providing a primary survey and care. The presence of fire, explosives, or hazardous materials may prompt an emergency move.
- Perform an urgent move when the patient requires immediate life-saving care, yet is in an unsafe environment. An urgent move may be necessary for moving a patient with an altered level of consciousness, with inadequate ventilation, or who is in shock, or in extreme weather conditions.
- Move a patient in an orderly, planned, and unhurried manner, selecting methods that involve the least amount of lifting and carrying.
- Transfer moves are used to transfer patients from a bed to a stretcher. Two examples of transfer moves are the direct carry method and the draw sheet method.
- Special equipment and protocols are needed when lifting or moving geriatric, bariatric, and neonatal patients.
- The wheeled ambulance stretcher is the most commonly used device to move and transport patients. Other devices that are used to lift and carry patients include portable stretchers,

flexible stretchers, backboards, basket stretchers (Stokes litter or Stokes basket), scoop stretchers, and stair chairs.

- It is essential to decontaminate patient-moving equipment after each use to prevent the spread of disease.
- While you are treating a patient, you must ensure the patient is properly positioned based on the chief complaint.
- Apply medical restraints when they are indicated according to your local protocols

and, depending on your jurisdiction, after receiving authorization from medical control.

- Whenever you are moving a patient, you must take special care to ensure no one is injured. You will learn the technical skills of patient packaging and handling through practice and training.
- Training and practice are also required to use all the equipment that is available to you. Practice each technique with your team often so you are able to perform the move quickly, safely, and efficiently.

Vital Vocabulary

backboard A long, flat board made of rigid rectangular material that is used to provide support to a patient who is suspected of having a hip, pelvic, spinal, or lower extremity injury; also called a long backboard, spine board, trauma board, and longboard.

bariatrics A branch of medicine concerned with the management (prevention or control) of obesity and allied diseases.

basket stretcher A rigid stretcher commonly used in technical and water rescues that surrounds and supports the patient yet allows water to drain through holes in the bottom; also called a Stokes litter.

diamond carry A carrying technique in which one provider is located at the head end of the stretcher or backboard, one at the foot end, and one at each side of the patient; each of the two providers at the sides uses one hand to support the stretcher or backboard so that all are able to face forward as they walk.

direct carry method A nonurgent move that is a method for moving a patient from a bed to a stretcher, in which a stretcher is positioned next to the bed and two providers move the patient.

direct ground lift A lifting technique that is used for patients who are found lying supine on the ground with no suspected spinal injury.

draw sheet method A nonurgent move that is a method for moving a patient from a bed onto a stretcher using a sheet on which the patient is lying.

emergency move A move in which the patient is dragged or pulled from a dangerous scene before a primary survey and care are provided.

extremity lift A lifting technique that is used for patients who are supine or in a sitting position on the ground with no suspected extremity or spinal injuries.

flexible stretcher A stretcher that is a rigid carrying device when secured around a patient but can be folded or rolled when not in use.

isolette A device used to transport a neonate in an ambulance; also called an incubator.

packaging The act of preparing a patient for movement as a unit by means of a backboard or similar stabilization device.

portable stretcher A stretcher with a strong, rectangular, tubular metal frame and rigid fabric stretched across it.

power grip A technique in which the stretcher or backboard is gripped by inserting each hand under the handle with the palm facing up and the thumb extended, fully supporting the underside of the handle on the curved palm with the fingers and thumb.

power lift A lifting technique in which the AEMT's back is held upright, with legs bent, and the patient is lifted when the AEMT straightens the legs to raise the upper body and arms.

rapid extrication technique A technique to move a patient from a sitting position inside a vehicle to supine on a backboard in less than 1 minute when conditions do not allow for standard immobilization.

scoop stretcher A stretcher that is designed to be split into two or four sections that can be fitted

around a patient who is lying on the ground or other relatively flat surface; also called an orthopaedic stretcher.

stair chair A lightweight folding device that is used to carry a responsive, seated patient up or down stairs.

wheeled ambulance stretcher A specially designed stretcher that can be rolled along the ground. A collapsible undercarriage allows it to be loaded into the ambulance; also called an ambulance stretcher.

- 7 The Human Body
- 8 Pathophysiology
- 9 Life Span Development

Chapter 7

The Human Body

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Preparatory

Applies fundamental knowledge of the EMS system, safety/well-being of the AEMT, and medical/legal and ethical issues to the provision of emergency care.

Anatomy and Physiology

Integrates complex knowledge of the anatomy and physiology of the airway, respiratory, and circulatory systems to the practice of EMS.

Pathophysiology

Applies comprehensive knowledge of the pathophysiology of respiration and perfusion to patient assessment and management.

KNOWLEDGE OBJECTIVES

1. Describe the structure of a cell. (p 263)
2. Describe how the structure of a cell membrane relates to movement into and out of the cell. (pp 263–264)
3. Discuss the four steps that make up the life cycle of the cell. (p 267)
4. Describe the process of cellular respiration. (pp 268–270)
5. Compare aerobic to anaerobic processes. (pp 268–269)
6. Discuss cell transport mechanisms, including diffusion, osmosis, facilitated diffusion, active transport, endocytosis, and exocytosis. (pp 270–272)
7. Explain the concept of fluid balance, as well as the purpose and mechanisms for maintaining homeostasis. (pp 273–274)
8. Identify the anatomy and describe the physiology of the skeletal and musculoskeletal systems. (pp 274–293)
9. Discuss the anatomy and physiology of the respiratory system. (pp 333–335)
10. Discuss the concepts of respiration and ventilation. (p 229)
11. Describe the process of gas exchange in the alveoli. (p 295)
12. Explain the brainstem's role in regulating respiration. (pp 299–300)
13. Describe the concept of hypoxic drive. (p 300)
14. Explain how the level of carbon dioxide in the blood and the blood's pH relate to ventilation. (pp 299–300)
15. Discuss the anatomy and physiology of the circulatory system. (pp 305–325)
16. Discuss the concepts of afterload, stroke volume, and cardiac output. (p 311)
17. Discuss the Starling law of the heart. (pp 311–312)
18. Discuss the anatomy and physiology of the nervous system. (pp 326–333)
19. Describe the anatomy and physiology of the integumentary system. (pp 333–335)

20. Explain the anatomy and physiology of the digestive system. (pp 336–340)
21. Discuss the anatomy and physiology of the endocrine system. (pp 340–343)

22. Describe the anatomy and physiology of the urinary system. (pp 343–344)
23. Discuss the anatomy and physiology of the genital system. (pp 344–347)

SKILLS OBJECTIVES

There are no skills objectives for this chapter.

Introduction

The study of **anatomy** is concerned with the structure of an organism and the components that make up the organism, in this case, the human body. Gross anatomy includes body parts that are generally visible to the naked eye: the bones, the muscles, and the organs. Microscopic anatomy involves components of the body that are small, often visible only through a microscope. **Physiology** examines the body functions of the living organism. With general knowledge of the structures and function of the body's systems, you will be able to better assess a patient as well as predict potential complications resulting from occult injuries (those not visible to the unaided eye).

Cells

Cells are the basic functional unit of the body. The cells of the body are extremely varied in their shape and function. Cells mature, or differentiate, over time. Through this process of differentiation, cells become specialized to perform a specific function. Cells with a common function are grouped closely together and are called tissues. Groups of tissues that all perform interrelated jobs form organs. A series of organs working together make up the body systems discussed in this chapter.

There are many types of cells (for example, muscle, nerve, kidney, and mucous gland cells) that perform specific functions. All cells, regardless of the type, perform excretion and respiration as part of their cellular functions. Cells communicate electrochemically within themselves, and externally with other cells. This is referred to as cellular signaling.

Cell Structure

The human body contains two general classes of cells. Sex cells (also called germ cells or reproductive cells) are discussed in more detail later in this chapter. Somatic cells (derived from the term *soma*, meaning body) include all the other cells in the human body. This section focuses on somatic cells.

Cells that make up the human body have a cell membrane, a nucleus, and cytoplasm (**FIGURE 7-1**). Structures within the cell organelles are specialized to perform specific functions. The nucleus contains genetic material and controls the activities of the cell.

Cell Membrane

The **cell membrane**, also called the plasma membrane, contains molecules that form pathways that allow movement into and out of the cell. These pathways allow signals from outside the cell to be

YOU are the Provider

Part 1

Your ambulance is notified about a shooting at a local apartment complex. As you inform dispatch that you are responding, you are advised that law enforcement is at the scene and the scene is secured. The dispatcher further states that you will have one patient, with multiple gunshot wounds in the chest and abdomen. As you arrive on scene, you find your patient lying left lateral on the ground, covered in blood.

1. How can knowledge of anatomy and physiology help you care for patients?
2. How can knowledge of medical terminology help you care for patients?

FIGURE 7-1 Cell structure. The cell is divided into nuclear and cytoplasmic compartments. The cytoplasm is packed with organelles.

© Jones & Bartlett Learning.

FIGURE 7-2 The phospholipid bilayer.

© Jones & Bartlett Learning.

detected and transmitted inside. When cells form tissues, the cell membrane assists by adhering the cell to other cells. The terms *intracellular* and *extracellular* refer to inside and outside the membrane, respectively.

The cell membrane is extremely thin and delicate, able to stretch to differing degrees. Tiny folds on the surface help the cell to increase its surface area. The cell membrane is composed of a bilayer (two layers), containing phosphate and fat molecules called phospholipids. This double layer of phospholipid molecules allows substances such as oxygen and carbon dioxide to easily pass through, while other substances cannot (**FIGURE 7-2**). This

means it is **semipermeable**; it allows certain elements to pass through while not allowing others to do so. In some instances, and often depending on various factors, only certain substances can enter or leave each cell (a condition known as selective permeability).

The cell membrane also has several proteins, classified as shown in **TABLE 7-1**.

Cytoplasm

The cytoplasm is the fluidlike material in which the contents of the cell are contained. Cytoplasm usually appears clear with scattered specks, although more powerful magnification reveals that it contains membranous networks, protein frameworks, and a cytoskeleton (cell skeleton).

Cytosol, which is the fluid portion of cytoplasm, contains mostly water, as well as glucose, amino acids, fatty acids, ions, lipids, proteins, **adenosine triphosphate (ATP)**, and waste products. Many of the chemical reactions necessary for life, including glycolysis, take place within the cytoplasm.

Organelles

The organelles within the cytoplasm perform specific functions. Each organelle accomplishes tasks related to cell structure, growth, maintenance, and

TABLE 7-1 Cell Membrane Proteins

Type of Membrane Protein	Description
Channel proteins	Allow passive passage into intracellular compartment. Some are gated ion channels, which open and close at specific times and only allow specific substances to pass.
Enzyme receptors	Act as sites where enzymes can bind (which occurs inside the cell); enzyme acts as a catalyst for a reaction.
Proteins that act as receptor sites	Binding site on outside of cell membrane; specific to certain molecules; binding causes a change in cellular function.
Identifier proteins	Identify cell as part of a particular organism; used by the immune system to determine self from nonself.
Carrier proteins	Bind to substances and transport them across the cell membrane.

© Jones & Bartlett Learning.

metabolism. The following organelles have specific actions that help the cell to carry out its activities:

- **Centrioles.** Cell division requires a pair of centrioles, which are cylindrical structures made up of short microtubules. During cell division, the centrioles form the spindle-shaped structure needed for movement of deoxyribonucleic acid (DNA) strands. Cardiac muscle cells, skeletal muscle cells, mature red blood cells (RBCs), and typical neurons (nerve cells) have no centrioles; therefore, these cells are incapable of dividing. The centrosome is the cytoplasm surrounding the centrioles. Microtubules of the cytoskeleton usually begin at the centrosome and radiate through the cytoplasm.
- **Cilia and flagella.** These structures extend from certain cell surfaces. Cilia are hairlike structures that move in a coordinated sweeping motion to sweep fluids over the surface of tissues. They are found on cells lining both the respiratory and reproductive tracts. The cells that line the respiratory tract have many cilia to move particles out of the airway. Flagella, which are longer than cilia, propel the cells to which they are attached. In humans, a flagellum appears as the tail of a sperm cell.
- **Ribosomes.** Ribosomes are composed of protein and ribonucleic acid (RNA). Ribosomes may be found either floating freely within the cytoplasm or attached to the endoplasmic reticulum (ER). Because their functions involve the formation of proteins, they are called the protein factories of the cell.
- **Endoplasmic reticulum.** The ER is a network of paths through which substances and proteins move. It is connected to the nuclear membrane and to the cell membrane. There are two types of ER: smooth and rough (**FIGURE 7-3**). The smooth ER lacks ribosomes and it can synthesize phospholipids and cholesterol, which are needed for the growth and maintenance of the cell membrane. The rough ER has ribosomes on its surface. Both free and fixed ribosomes synthesize proteins via instructions from messenger RNA.
- **Golgi apparatus.** This organelle, also called the Golgi complex, consists of a stack of several flattened sacs. These pancakelike structures are hollow, with cavities called cisternae inside them. The Golgi apparatus deals primarily with proteins synthesized on the ribosomes. The end of the Golgi apparatus is specialized to receive glycoproteins, modifying them by removing or adding sugar molecules. The Golgi apparatus has three main functions: (1) concentrating and packaging secretions (such as hormones or enzymes) that are released for secretion out of the cell, (2) packaging special enzymes inside vesicles for use in the cytosol, and (3) renewing or modifying the cell membrane.
- **Lysosomes.** These tiny sacs dispose of cell wastes using enzymes to break down nutrients

FIGURE 7-3 Rough endoplasmic reticulum with fixed ribosomes on its outer surface.

© Jones & Bartlett Learning.

and foreign particles (such as bacteria). They also destroy older, worn-out parts of the cell. This breakdown process requires the use of powerful enzymes. It often generates toxic chemicals capable of damaging or killing the cell. Lysosomes are specialized vesicles that provide an isolated environment for potentially dangerous chemical reactions. They are produced close to the Golgi apparatus and contain digestive enzymes.

- **Microfilaments.** The smallest of the cytoskeletal elements, microfilaments are composed of the proteins actin and myosin. They are typically found in muscle cells. Microfilaments provide cell movement and contraction via interaction with actin and myosin. This process can also change the shape of the entire cell.
- **Mitochondria.** All cells in the body, except for mature RBCs, have between 100 and a few thousand organelles called mitochondria (singularly called a mitochondrion). Mitochondria have double membranes that play the central role in the production of energy (via ATP). The number of mitochondria in each cell varies,

based on the cell's energy demands; mitochondria are the powerhouses of cells. The liver, kidneys, and muscles have a large number of mitochondria in their cells because they use ATP (energy) at a high rate.

A mitochondrion is surrounded by two membranes similar in structure to the plasma membrane. The outer mitochondrial membrane is smooth. The inner mitochondrial membrane has a series of folds called cristae. The central fluid-filled cavity is called the matrix and is enclosed by the inner membrane and cristae.

Mitochondria can migrate through the cytoplasm of a cell and are able to reproduce themselves. Mitochondria contain their own DNA, but in a more primitive form than that found within the cell nucleus.

- **Peroxisomes.** These sacs have enzymes that speed up many biochemical reactions. They are abundant in the liver and kidney cells, and their diverse actions include the synthesis of bile acids, detoxification of hydrogen peroxide or alcohol, and breakdown of lipids and biochemicals.
- **Thick filaments.** These organelles are relatively massive bundles of subunits composed of the protein myosin. Thick filaments appear in muscle cells only, where they interact with actin filaments to produce powerful contractions.
- **Vesicles.** Also known as vacuoles, these sacs are formed when a part of a cell membrane folds inward, establishing a bubblelike structure within the cytoplasm. Vesicles contain various liquid or solid materials that formerly existed outside of the cell membrane.

Nucleus

The nucleus is the largest structure in the cell. It serves as the control center and is located somewhere in the middle. It contains DNA, or genetic material, that controls cell activities. A single nucleus stores all required information that directs the synthesis of the 100,000 proteins in the human body. A cell without a nucleus cannot repair itself. It will disintegrate within 3 to 4 months. The nucleus contains the genetic instructions needed to synthesize the proteins that determine cell structures and functions. These instructions are stored in the **chromosomes**. These structures consist of DNA and

various proteins that control and access genetic information. Most cells contain a single nucleus, except for skeletal muscle cells (with multiple nuclei) and mature RBCs (with no nuclei).

The nucleus of a cell is usually round and is enclosed in a double nuclear envelope, with inner and outer lipid membranes. This envelope also has a protein lining, allowing certain molecules to exit the nucleus. Inside the nucleus is a fluid called nucleoplasm that suspends the following structures:

- **Nucleolus.** A mini nucleus made up mostly of RNA and protein molecules, with no surrounding membrane. Ribosomes form in the nucleolus and migrate out to the cell's cytoplasm.
- **Chromatin.** Loosely coiled DNA and protein fibers that condense, forming chromosomes. The DNA controls protein synthesis, and when the cell starts to divide, the chromatin fibers coil tightly to form the chromosomes.

Life Cycle of the Cell

The life cycle of the cell is regulated via stimulation from hormones or growth factors. Disruption of the cycle can affect the health of the body. Most human cells divide between 40 to 60 times before they die. The life cycle of a cell includes the following four steps:

1. **Interphase.** The cell obtains nutrients to grow and duplicate.
2. **Cell division (mitosis).** The nucleus divides.
3. **Cytoplasmic division (cytokinesis).** The cytoplasm divides.
4. **Differentiation.** The cell becomes specialized.

Interphase

A cell must grow and duplicate most of its contents before it can actively divide. *Interphase* describes this period of preparation to divide. During interphase, the cell manufactures new living material by duplicating membranes, lysosomes, mitochondria, and ribosomes. The cell also replicates its own genetic material.

Cell Division and Cytoplasmic Division

The two types of cell division are meiosis and mitosis/cytokinesis. **Meiosis**, which occurs in the production of eggs (oocytes) and sperm, reduces

the number of chromosomes by one-half, from 46 to 23. When a sperm and egg unite, the resulting fertilized egg will have a total of 46 chromosomes.

In the rest of the body, cell numbers are increased by **mitosis**, the division of the nucleus of a cell, and cytokinesis, the division of the cytoplasm of a cell. During mitosis, a cell duplicates itself into daughter cells—identical copies of the original cell. The nucleus must divide precisely so an accurate copy of the DNA can be made by the new cell. Most of the cells of the human body, except for sex cells and RBCs, reproduce by mitosis.

Cytoplasmic division, or **cytokinesis**, begins during the second phase of mitosis, when the cell membrane constricts down the middle portion of the cell. This process continues through the fourth phase to divide the cytoplasm. The two newly formed nuclei are then separated and almost one-half of the organelles are distributed into each new cell.

Differentiation

Differentiation, the process of specialization of a cell, makes each cell unique. New cells must be generated for growth and tissue repair to occur. A **stem cell** can divide repeatedly without specializing. Stem cells can either divide into two identical daughter cells or divide so that one daughter cell becomes partially specialized (progenitor cells). In the human body, all differentiated cell types are created because of the variance of stem and progenitor cells. Researchers are exploring the use of stem cells in the treatment of disease.

Cell Division and Cancer

Cell division and growth normally occur at approximately the same rate as cell death. However, when cell division and growth occur at a higher rate than the cell death rate, tissues enlarge. A **neoplasm** (tumor) is a mass of tissue produced by abnormal cell growth and division. A tumor is *benign* when it remains within the epithelium (a capsule made of connective tissue). A benign tumor seldom becomes life threatening and can usually be surgically removed if it affects tissue function, or simply observed if it is not causing a problem.

In contrast, a *malignant* tumor spreads into surrounding tissues in a process called invasion. The tumor of origin (the primary tumor or primary neoplasm) may result in malignant cells traveling

to other organs or tissue to establish secondary tumors. This process, called metastasis, is not easily controlled: cancer develops and exhibits mutations disrupting normal cell growth. Usually, all tumor cells are daughter cells of just one malignant cell. Malignancy often occurs when a normal gene mutates. These modified genes are called oncogenes. Cancer often begins where stem cells divide. This is because there is a greater chance of error the more frequently that chromosomes are copied for cell division.

Cancer cells change shape as they grow and gradually resemble normal cells less and less. If tumor cells penetrate blood vessels, then they circulate throughout the body. If tumor cells enter the lymphatic system, then they build up in lymph nodes. The presence of tumor cells stimulates the growth of new blood vessels where the cells situate themselves, which supplies them with more nutrients and accelerates their growth and further metastasis.

As metastasis increases, organ function changes. Cancer cells grow and multiply by taking nutrients and space from normal cells, causing weight loss in

most patients with cancer as the normal cells deteriorate. Death may occur when cancer cells compress vital organs or replace healthy cells in vital organs.

Cellular Respiration

Cells use glucose and oxygen to release energy from organic compounds in a process called **cellular respiration**. This process requires three types of reactions: glycolysis, the Krebs cycle, and the electron transport chain. The end products of cellular respiration are carbon dioxide (CO_2), water (H_2O), and the high-energy molecule ATP. Energy is released from ATP when bonds between phosphate molecules (that are part of the ATP molecule) break to release their stored energy.

Glycolysis

Glycolysis, which occurs in the cytosol of the cytoplasm, is a process that involves a series of enzymatically catalyzed reactions in which glucose is broken down to yield lactic acid and pyruvic acid (**FIGURE 7-4**). Glucose is broken down into

FIGURE 7-4 During anaerobic metabolism, which occurs in the cytoplasm, the breakdown of glucose results in lactic acid. During aerobic metabolism, which occurs in the mitochondrion, the breakdown of glucose results in carbon dioxide, water, and adenosine triphosphate.

2 three-carbon pyruvic acid molecules, gaining two ATP molecules and releasing high-energy electrons. Glycolysis does not require oxygen and therefore is a form of **anaerobic metabolism**.

If oxygen is present in the right amounts, pyruvic acid can enter the more energy-efficient pathways of aerobic respiration. These pathways are located in the mitochondria. Aerobic reactions yield as many as 36 ATP molecules per glucose molecule. Most result from the aerobic phase, with only two resulting from glycolysis. Approximately one-half of the released energy is used for ATP synthesis, while the rest becomes heat.

Words of Wisdom

When insufficient oxygen is available, respiration can occur in the form of anaerobic respiration. In this scenario, pyruvic acid converts to lactic acid. This can result in lactic acidosis. Pyruvic acid is created from lactic acid when oxygen is present.

Krebs Cycle

The Krebs cycle, also called the citric acid cycle or tricarboxylic acid cycle, is a form of **aerobic metabolism**. It is a sequence of enzymatic reactions involving the metabolism of carbon chains of glucose, fatty acids, and amino acids to yield carbon dioxide, water, and high-energy phosphate bonds (ATP). It is important to note that this stage is an aerobic process; the Krebs cycle occurs in the presence of oxygen. The three-carbon pyruvic acids enter the mitochondria, each losing a carbon atom. The molecules then combine with a coenzyme to form a two-carbon acetyl coenzyme A and release more high-energy electrons. Each acetyl coenzyme A combines with a four-carbon oxaloacetic acid to form a six-carbon citric acid.

A series of reactions removes two carbons, synthesizes one ATP molecule, and releases more high-energy electrons. When food is ingested, large macromolecules are broken down to simple molecules. Proteins are broken down into amino acids, carbohydrates are broken down into simple sugars (glucose), and fats are broken down into both glycerol and fatty acids. The breakdown of simple molecules to acetyl coenzyme A is accompanied by the

production of limited amounts of ATP (via glycolysis) and high-energy electrons.

As already discussed, glucose was converted to pyruvic acid during glycolysis. Glycerol and amino acids are also broken down into pyruvic acid. In differing ways, all of these processes result in acetyl coenzyme A. Complete oxidation of acetyl coenzyme A to H_2O and CO_2 produces high-energy electrons, which yield greater amounts of ATP via the electron transport chain. In the Krebs cycle, the process of oxidation provides more molecules of ATP.

After glycolysis and the Krebs cycle have occurred, a total of four molecules of ATP have been produced—two from glycolysis and two from the Krebs cycle.

When oxygen is absent, respiration can still occur via an anaerobic process. In this case, glycolysis occurs, but because oxygen is absent, pyruvic acid converts to lactic acid. Anaerobic processes can ultimately lead to lactic acidosis if they occur in excess. Lactic acidosis can develop with shock due to insufficient oxygen.

Electron Transport Chain

In this last step, 34 molecules of ATP are produced in an aerobic process. High-energy electrons still contain most of the chemical energy of the original glucose molecule. Special carrier molecules bring them to enzymes that store most of the remaining energy in more ATP molecules; heat and water are also produced. Oxygen is the final electron acceptor in this step; therefore, the overall process is termed aerobic respiration.

For cellular respiration, glucose and oxygen are required. This process produces carbon dioxide, water, and energy. Nearly one-half of the energy is recaptured as high-energy electrons stored in the cells through the synthesis of ATP.

Each ATP molecule has a chain of three chemical groups. These groups are called phosphates. Some of the energy is recaptured in the bond of the end phosphate. When energy is later needed, the terminal phosphate bond breaks to release the stored energy. Cells use ATP for many functions, including active transport and the synthesis of needed compounds.

The end result of glycolysis, the Krebs cycle, and the electron transport chain is 38 molecules of ATP.

Cellular Transport Mechanisms

Cellular transport mechanisms refer to how materials enter and exit the cell. Such movement relates to fluid administration, discussed in Chapter 13, *Vascular Access and Medication Administration*.

Each body compartment is separated by a membrane. Recall that the cell membrane is selectively permeable, meaning it allows some substances to pass through it, but not others. This selective permeability helps maintain homeostasis, the maintenance of a stable internal physiologic environment including a stable temperature, fluid balance, and pH balance. Various enzymes, glucose molecules, and electrolytes freely pass in and out of the cell. **Electrolytes** are chemicals that are dissolved in the blood and are made up of salt or acid substances that become ionic conductors when dissolved in a solvent such as water.

Selective permeability also allows for differences in concentrations between intracellular and extracellular environments. (Normally, if there are unequal concentrations on either side of a cell membrane, they will move to balance the concentration on both sides of the membrane.) The concentration of the compounds (water and electrolytes) as well as the concentration of the charges (positive or negative) carried on the atoms determines movement, and the natural tendency is to move from an area of higher concentration to an area of lower concentration. The difference in concentrations of a substance on either side of the cell membrane is called the **concentration gradient**. The cell membrane plays an important role in the flow down a concentration gradient; it determines whether materials are allowed to pass through. Several mechanisms, such as diffusion, osmosis, facilitated diffusion, active transport, endocytosis, and exocytosis, allow material to pass through the cell wall.

Diffusion

Diffusion is the passive movement of a **solute** (a particle such as salt that is dissolved in a solvent) moving from an area of higher concentration to an area of lower concentration until an even distribution of particles is achieved (**FIGURE 7-5**). Small molecules diffuse more easily than large ones.

FIGURE 7-5 Diffusion.

© Jones & Bartlett Learning.

Watery solutions diffuse more rapidly than thicker, viscous solutions. Many of the cell's nutrients enter the cell by diffusion. Oxygen and carbon dioxide are examples of substances that can move by diffusion.

To visualize diffusion, imagine that too many people show up for a theater performance. The theater manager decides to open another seating area to accommodate the crowd. Patrons (charges or compounds) are concentrated in a small area (the cell) outside the door (the cell membrane) leading to the new seating area. When the theater manager opens the door, patrons can move through it (selective cell membrane permeability) from the congested area (down a concentration gradient). The patrons spread themselves out evenly (diffuse) throughout the total area, with some choosing to stay behind in the original seating area as others move into the new area, until all patrons have an equal amount of room.

Diffusion in the lungs and pulmonary vasculature occurs as the capillaries that surround the alveoli, which contain a high oxygen content, circulate blood that is high in carbon dioxide. Carbon dioxide leaves the blood and moves into the alveoli while oxygen moves in the opposite direction, from the alveoli into the blood, until the concentrations of each are equal on either side of the membrane. For this reason, the amount of carbon dioxide that remains in the arterial blood is almost equal to the amount of carbon dioxide that is exhaled.

Filtration

Another method for moving substances is **filtration**. The kidneys essentially filter compounds from the blood; water containing dissolved compounds enters the tubules of the kidney and then continues on while the dissolved compounds remain behind. The end result is that wastes have been removed

from the blood (and thereby, from the body) and are excreted in the urine.

Facilitated Diffusion

Facilitated diffusion is the process in which a carrier molecule moves substances in or out of cells from areas of high concentration to areas of lower concentration (**FIGURE 7-6**). Energy is not required; the number of molecules transported is directly proportional to the amount of concentration. An example of a substance that enters the cell by facilitated diffusion is glucose. The hormone insulin is required to move glucose into the cells.

Active transport is the movement of a substance against a concentration or a gradient such as the cell membrane, opposite the normal movement of diffusion; substances move toward the side with a higher concentration. Active transport requires energy as well as some type of carrier mechanism. At times, the active transport mechanism may exchange one substance for another.

Endocytosis and exocytosis are processes that use energy from the cell to move substances into or out of the cell without crossing the cell membrane. In endocytosis, a secretion from the cell membrane moves particles too large to enter the cell by other processes within a vesicle of the cell. The three

FIGURE 7-6 A. Facilitated diffusion involves particles moving from an area of higher concentration toward an area of lower concentration with the assistance of a protein. **B.** Active transport uses energy from adenosine triphosphate (ATP) to open a pathway for compounds to move against a concentration gradient.

Abbreviation: ADP, adenosine diphosphate.

forms of endocytosis are pinocytosis, phagocytosis, and receptor-mediated endocytosis. Pinocytosis (“cell drinking”) involves cells taking in small liquid droplets from the surrounding cell environment with a small indentation of the cell membrane. Phagocytosis (“cell eating”) involves cells taking in solids instead of liquids, by engulfing the foreign particle. Receptor-mediated endocytosis involves the movement of specific kinds of particles into the cell, with protein molecules extending through part of the cell membrane to the outer surface. The opposite process to endocytosis is exocytosis, in which a substance stored in a vesicle is secreted from the cell.

An example is the cell’s transport of sodium and potassium across the membrane. The cell allows two potassium ions to enter the cell while three sodium ions exit (this is called the sodium/potassium pump). If there is an inadequate amount of potassium present, sodium will not be transported as needed, leading to swelling and potential rupture.

Words of Wisdom

Think of sitting in a rowboat in a strong current. As long as you move in the direction the current is flowing, no energy is required. If you wish to go against the current, you must expend energy to row against the current. This energy expenditure is similar to active transport: you must expend energy to move against the concentration gradient.

Osmosis

Osmosis is the passive movement of a solvent, or liquid, from an area of low solute concentration to one of high concentration through a selectively permeable membrane. The membrane is permeable to the solvent but not to the solute. Movement generally continues until the concentrations of the solute equalize on both sides of the membrane (**FIGURE 7-7**). **Osmotic pressure** is a measure of the tendency of water to move by osmosis across a membrane. The osmotic pressure of a solution, or the ability to affect the movement of water, is osmolality.

The concentration of a solution, or ability to draw or give water, is its **tonicity** (**FIGURE 7-8**). A solution with a higher solute concentration compared

FIGURE 7-7 A. An example of osmosis occurs when a permeable bag of salt water is immersed in a solution of pure water. **B.** Water moves into the bag (toward the area with lower water concentration) equalizing the concentrations on each side of the membrane.

© Jones & Bartlett Learning.

with another solution is **hypertonic**, and a solution with a lower solute concentration is **hypotonic**. An **isotonic** solution is one in which there is an equal concentration of solutes and liquid on either side of the membrane. If too much water moves out of a cell, the cell shrinks abnormally, a process known as **crenation**. If too much water enters a cell, it will swell and burst, a process known as **lysis**.

Body Fluid Balance

The total body water content of the average adult ranges from 50% to 70% of total body weight, depending on age and sex. A newborn’s total body water content may be as high as 75% to 80% of total body weight.

Body fluid is divided into two main compartments: intracellular fluid and extracellular fluid. **Intracellular fluid (ICF)** exists within individual cells and equals approximately 40% to 45% of total body weight. The ICF makes up approximately 75% of all body fluid. **Extracellular fluid (ECF)** exists outside of the cell membranes. It equals approximately 15% to 20% of the total body weight, or 25% of all body fluid. ECF is further divided into intravascular fluid and interstitial fluid. **Intravascular fluid (plasma)**, the fluid portion of blood, is found within the blood vessels and accounts for approximately 4.5% of total body weight. **Interstitial fluid** is located outside of the blood vessels, in the spaces between the body’s cells. It accounts for approximately 10.5% of total

**FIGURE 7-8** Tonicity.

© Jones & Bartlett Learning.

body weight. There is a delicate balance among the various fluid compartments of the body that is essential to maintain homeostasis.

If fluid is lost from anywhere in the body, there can be serious ramifications because this disturbs the balance among various fluid compartments (homeostasis). The result can be shock. Under normal conditions, the total volume of water in the body and its distribution in the body compartments remain relatively constant, even though there are fluctuations in the amount of water that enters and is excreted from the body each day. **Fluid balance** is the process of maintaining homeostasis through equal intake (water taken into the body) and output (water excreted from the body) of fluids.

There are mechanisms in the body that maintain the balance between what is taken in and what is excreted (**TABLE 7-2**). For example, when the fluid volume decreases, the pituitary gland secretes antidiuretic hormone (ADH) (**FIGURE 7-9**). ADH causes the kidney tubules to reabsorb more water into the blood and excrete less urine, allowing fluid volume in the body to build up. Thirst also

**FIGURE 7-9** The role of antidiuretic hormone in regulating fluid levels.

© Jones & Bartlett Learning.

regulates fluid intake. The sensation of thirst occurs when body fluids become decreased, stimulating a person to take in more fluids. Conversely, when too many fluids enter the body, thirst decreases, the

kidneys are activated, and more urine is excreted, eliminating the excess fluid.

It is important to maintain the proper balance of fluids and electrolytes within the body, because this is necessary for life. A person's body can become depleted of fluids and electrolytes for several reasons, including severe burns or dehydration. The body can maintain fluid balance by shifting water from one compartment to another. Water moves in response to osmotic forces as well as hormonal stimuli such as ADH. For a patient whose fluids or electrolytes are depleted, rapid restoration of fluid balance may mean the difference between life and death.

Organ Systems

An organ is composed of at least two kinds of tissue that are organized to perform a more complex task than a single tissue can. An organ system is composed of at least two kinds of organs that, again, are organized to perform a more complex task than a single organ can. The 12 major organ systems of the body include the integumentary, skeletal, muscular, nervous, endocrine, circulatory, lymphatic, immune, respiratory, digestive, urinary, and reproductive systems (**FIGURE 7-10**). All of these except the lymphatic system are shown in the figure.

The Skeletal System: Anatomy

The **skeleton** gives us our recognizable human form and protects our vital internal organs. Bones constitute the major structure of the skeletal system. Cartilage, tendons, and ligaments are important connective tissues that work with bones to provide the support framework of the skeleton (**TABLE 7-3**).

A **tendon** is a specialized tough cord or band of dense white connective tissue that connects muscle to bone. A **ligament** is a tough white band of tissue that connects bones to each other. Tendons and ligaments are composed of densely packed fibers of collagen, a twisted, ropelike protein. A sprain occurs when the bone ends partially or temporarily dislocate and the supporting ligaments are partially stretched or torn.

When a muscle contracts, tendon pulls on bone, resulting in motion at the joint, the point

where two or more bones come together, allowing movement to occur. A strain, or muscle pull, occurs when a muscle is stretched or torn. A strain results in pain, swelling, and bruising of surrounding soft tissues. No ligament or joint damage occurs with a strain. Sprains and strains are graded based on their severity and physical findings during examination.

Shiny connective tissue called **cartilage** is lubricated by a transparent viscous joint fluid (synovial fluid). It receives nutrients through diffusion from the outer covering of the cartilage or from the synovial fluid.

Bones

Bones are classified according to their shape, as long bones, short bones, or flat bones. Long bones include the femur, tibia, fibula, ulna, radius, and humerus. Short bones include the bones of the wrist and ankle. Flat bones include certain skull bones, ribs, the sternum, and the scapulae. There are also irregular bones, which have unique shapes and are designed to perform a specific function. These bones include the mandible, many facial bones, and those that comprise the vertebrae in the spine and pelvis.

Special Populations

Fractures are more common in older people because of decreased bone mineral density, resulting in weaker bones.

Words of Wisdom

Dysfunction or suppression of the bone marrow may develop in people who have adverse reactions to certain drugs, such as nonsteroidal anti-inflammatory drugs (NSAIDs), or who undergo chemotherapy treatments for cancer. Use of chemotherapy and NSAIDs can result in anemia caused by a decrease in the number of RBCs produced by the marrow, increased susceptibility to infection caused by a decrease in the number of infection-fighting white blood cells (WBCs), and a tendency for internal or external bleeding caused by a decrease in the number of platelets (blood-clotting cells).

TABLE 7-3 Support Structures Within the Skeletal System

Name	Function
Ligament	Connects bone to bone
Tendon	Connects muscle to bone
Cartilage	Cushion between bones

© Jones & Bartlett Learning.

Long bones consist of a shaft, the **diaphysis**; the ends, or **epiphyses**; and the growth plate or epiphyseal plate (the physis), which is the major site of bone elongation during the growth and development phase (FIGURE 7-11). The epiphyseal plate is located adjacent to the epiphysis. The **periosteum**, which consists of a double layer of connective tissue, lines the outer surface of the bone, and the inner surfaces are lined with **endosteum**.

The diaphysis of many bones includes the **medullary cavity**, an internal cavity that contains a substance known as **bone marrow**. In adults, most bone marrow in the long bones in the extremities contains adipose (fat) tissue and is, therefore, called yellow marrow. The bones of the axial skeleton and girdles contain red marrow, where most RBCs are manufactured.

The two main types of bone are compact bone and cancellous bone. Compact bone is mostly solid, with few spaces; **cancellous bone** consists of a lacy network of bony rods called **trabeculae**. The trabeculae are oriented along the lines of stress to increase the weight-bearing capacity of the long bones.

Joints

Wherever two long bones come in contact, a **joint (articulation)** is formed. A joint consists of the ends of the bones that make up the joint and the surrounding connecting and supporting tissue (FIGURE 7-12). Many joints in the body are named by combining the names of the two bones that form that joint. For example, the sternoclavicular joint is the articulation between the sternum and the clavicle. Most joints allow motion (for example, the knee, hip, and elbow), whereas some bones fuse with one another at joints to form a solid, immobile, bony structure. For example, the skull is composed of several bones that fuse as a child grows. Some joints

**FIGURE 7-11** The components of the long bone.

© Jones & Bartlett Learning.

have slight, limited motion in which the bone ends are held together by fibrous tissue. Such a joint is called a **symphysis**.

The bone ends of a joint are held together by a fibrous sac called the **joint capsule**. This sac is composed of tissue called ligaments (which connect bone to bone). At certain points around the circumference of the joint, the capsule is lax and thin so motion can occur. In other areas, it is quite thick and resists stretching or bending. A joint such as the sacroiliac joint that is virtually surrounded by tough, thick ligaments will have little motion, whereas a joint such as the shoulder, with fewer ligaments, will be free to move in almost any direction (and will, as a result, be more susceptible to dislocation). On the inner lining of the joint capsule is the **synovial membrane**. This special tissue makes a thick lubricant called **synovial fluid**. This oil allows the ends of the bones to glide over each other, as opposed to rubbing and grating over each other. Synovial fluid contains WBCs to fight infections and provides nourishment to the cartilage covering the bone.

FIGURE 7-12 A joint consists of bone ends, the fibrous joint capsule, the synovial membrane, and ligaments. The degree to which a joint can move is determined by how the ligaments hold the bone ends and by the configuration of the bones themselves.

© Jones & Bartlett Learning.

FIGURE 7-13 The shoulder is an example of a ball-and-socket joint.

© Jones & Bartlett Learning.

The degree to which a joint can move is determined by the extent to which the ligaments hold the bone ends together and also by the configuration of the bone ends themselves. The shoulder joint is a **ball-and-socket joint** (**FIGURE 7-13**). Possible motions at a ball-and-socket joint include flexion, extension, abduction, adduction, rotation, and circumduction (a circular movement such as wind-milling the arms). The finger joints, elbow, and knee are **hinge joints**, with motion largely restricted to one plane (**FIGURE 7-14**). They primarily flex (bend) and extend (straighten).

The biceps muscle, for example, has its origin on the scapula; the biceps tendon passes over the

FIGURE 7-14 The elbow joints are hinge joints, which allow motion primarily in one plane (flexion and extension).

© Jones & Bartlett Learning.

head of the humerus, where it fuses with the body of the biceps muscle; at the distal end of the biceps, a tendon passes over the anterior surface of the elbow and inserts on the radius. Thus, when the biceps muscle contracts, the force causes the elbow to bend (flex). Rotation is not possible because of the shape of the joint surfaces and the strong restraining ligaments on both sides of the joint.

Although the amount of motion varies from joint to joint, all joints have a limit beyond which motion cannot occur. When a joint is forced beyond this limit, damage to some structure (bones, joints, or ligaments) occurs.

The Axial Skeleton

The skeletal system is divided into two main portions: the **axial skeleton** and the **appendicular skeleton**. The axial skeleton forms the foundation on which the arms and legs are hung. The axial skeleton is composed of the skull, thoracic cage, and vertebral column. The arms and legs, their connection points, and the pelvis make up the appendicular skeleton (**FIGURE 7-15**). The brain lies within the skull. The heart, lungs, and great vessels are enclosed in the **thorax**, also called the thoracic cavity, which is part of the torso. Much of the liver and spleen are protected by the lower ribs. The spinal

FIGURE 7-15 The 206 bones of the skeleton give us our form, protect our vital organs, and allow us to move. The axial skeleton runs in a straight line from the head to the pelvis. The appendicular skeleton is made up of the arms and legs and the pelvis.

© Jones & Bartlett Learning.

cord is contained within and protected by a bony spinal canal formed by the vertebrae.

The 206 bones of the skeleton provide a framework for the attachment of muscles. The skeleton is also designed to allow motion of the body. Bones come in contact with one another at joints where, with the help of muscles, the body is able to bend and move.

The Skull

At the top of the axial skeleton is the **skull**, which consists of 28 bones in three anatomic groups: the auditory ossicles, the **cranium**, and the face (**FIGURE 7-16**). The six **auditory ossicles** function in hearing and are located, three on each side of the head, deep within cavities of the temporal bone. The remaining 22 bones comprise the cranium and the face.

At the base of the temporal bone is a cone-shaped section of bone known as the **mastoid process**. This area is an important site for attachment of various muscles.

The **cranial vault** consists of the eight bones that encase and protect the brain: the parietal, temporal, frontal, occipital, sphenoid, and ethmoid bones. The brain and the spinal cord are connected through a large opening at the base of the skull called the **foramen magnum**.

The bones of the skull are connected together at special joints known as **sutures** (**FIGURE 7-17**). The paired parietal bones join together at the sagittal suture. The parietal bones abut the frontal bone at the coronal suture. The occipital bone attaches to the parietal bones at the lambdoid suture. Fibrous tissues called **fontanelles**, which soften and expand during childbirth, link the sutures. The tissues felt through the fontanelles are layers of the scalp and thick membranes overlying the brain. Under normal conditions, the brain may not be felt through the fontanelles. By the time a child reaches age 2 years, the sutures should have solidified and the fontanelles closed.

The Floor of the Cranial Vault

Viewed from above, the floor of the interior of the skull, or cranial vault, is divided into three compartments: the anterior fossa, middle fossa, and posterior fossa (**FIGURE 7-18**).

The **crista galli** forms a prominent bony ridge in the center of the anterior fossa and is the point

FIGURE 7-16 The skull consists of 28 bones in three anatomic regions: the auditory ossicles, the cranium, and the face.

FIGURE 7-18 The floor of the cranial vault and its anatomy.

© Jones & Bartlett Learning.

of attachment of the meninges, the three layers of membranes—the dura mater, arachnoid, and pia mater—that surround the brain. On either side of the crista galli is the **cribriform plate** of the ethmoid bone, the horizontal bone that is perforated with numerous openings (**foramina**) for the passage of the olfactory nerve filaments from the nasal cavity. The **olfactory nerve**, the cranial nerve for smell, sends projections through the foramina in the cribriform plate and into the **nasal cavity**, the chamber

inside the nose that lies between the floor of the cranium and the roof of the mouth.

The Facial Bones

The frontal and ethmoid bones are part of both the cranial vault and the face. The 14 facial bones form the structure of the face, without contributing to the cranial vault. These bones include the **maxillae**, mandible, **zygoma**, palatine, nasal, lacrimal, vomer, and inferior nasal concha bones (**FIGURE 7-19**).

FIGURE 7-19 The skull and its components. **A.** Front view. **B.** Bottom view.

© Jones & Bartlett Learning.

Words of Wisdom

Fractures of the cribriform plate result in leakage of cerebrospinal fluid (CSF) from the nose. CSF is the fluid that bathes and provides hydraulic cushioning to the brain and spinal cord. Leakage of clear, watery fluid from the nose following head trauma suggests leakage of CSF.

The facial bones protect the eyes, nose, and tongue and provide attachment points for the muscles that allow chewing. The zygomatic process of the temporal bone and the temporal process of the zygomatic bone form the zygomatic arch (**FIGURE 7-20**). The zygomatic arch lends shape to the cheeks.

Bones of the Orbit

The **orbit** is the cone-shaped fossa that encloses and protects each eye. In addition to the eyeball and muscles that move it, the orbit contains blood vessels, nerves, and fat. The frontal, sphenoid, zygomatic, maxilla, lacrimal, ethmoid, and palatine bones each form portions of the orbits.

A blow to the eye may result in fracture of the floor of the orbit. This bone is extremely thin and breaks easily. The result is transmission of forces

FIGURE 7-20 The zygomatic arch.

© Jones & Bartlett Learning.

away from the eyeball itself to the bone. Blood and fat then leak into the maxillary sinus below. This type of fracture is called a blowout fracture.

Bones of the Nose

The nasal cavity comprises portions of several of the facial bones, including the frontal, nasal, sphenoid, ethmoid, inferior nasal concha, maxilla, palatine,

and vomer bones. The **nasal septum** is the separation between the nostrils and is located in the midline. Often, it bulges slightly to one side or the other. The external portion of the nose is formed mostly of cartilage.

Several of the bones associated with the nose contain cavities known as the **paranasal sinuses**, or sinuses (**FIGURE 7-21**). These hollowed sections of bone are lined with mucous membrane and decrease the weight of the skull as well as provide resonance for the voice. The contents of the sinuses drain into the nasal cavity. **Sinusitis** is an inflammation of the paranasal sinuses that is relatively common. Sinusitis may range in severity from a simple upper respiratory tract infection consisting of headache and nasal drainage to a potentially life-threatening brain infection, depending on the extent of the infection and which sinuses are affected.

The Mandible and Temporomandibular Joint

The **mandible** is the large movable bone comprising the lower jaw and containing the lower teeth. Numerous muscles of chewing attach to the mandible. The posterior condyle of the mandible articulates with the temporal bone at the **temporomandibular joint (TMJ)**, allowing movement of the mandible.

FIGURE 7-21 The paranasal sinuses.

© Jones & Bartlett Learning.

The Hyoid Bone

The **hyoid bone** “floats” in the superior aspect of the neck just below the mandible. It is not actually part of the skull, but it supports the tongue and serves as a point of attachment for many important neck and tongue muscles.

The Neck

The neck is supported by the cervical spine, or the first seven vertebrae in the spinal column (C1 through C7). The spinal cord exits from the foramen magnum and lies within the spinal canal formed by the vertebrae. The upper part of the esophagus and the **trachea** lie in the midline of the neck. The carotid arteries are found on either side of the trachea, along with the jugular veins and several nerves.

Several useful landmarks can be palpated and seen in the neck (**FIGURE 7-22**). The most obvious is the firm prominence in the center of the anterior surface commonly known as the Adam’s apple. This prominence is the upper part of the **thyroid cartilage** and is more prominent in men than in women. The lower portion is the **cricoid cartilage**, a firm ridge of cartilage inferior to the thyroid cartilage, which is somewhat more difficult to palpate. Between the thyroid cartilage and the cricoid cartilage in the midline of the neck is a soft depression, the **cricothyroid membrane**. This is a thin sheet of connective tissue (**fascia**) that joins the two cartilages.

FIGURE 7-22 The principal structures of the neck include the trachea, along with many blood vessels, muscles, and nerves.

© Jones & Bartlett Learning.

The cricothyroid membrane is covered at this point only by skin.

Inferior to the larynx, several additional firm ridges are palpable in the anterior midline. These ridges are the cartilage rings of the trachea. The trachea connects the larynx with the main air passages of the lungs (the bronchi). On either side of the lower larynx and the upper trachea lies the thyroid gland. Unless it is enlarged, this gland is usually not palpable.

Pulsations of the carotid arteries are easily palpable in a groove approximately one-half inch (1 cm) lateral to the larynx. Lying immediately adjacent to these arteries, but not palpable, are the internal jugular veins and several important nerves. Lateral to these vessels and nerves lie the **sternocleidomastoid muscles**, which allow movement of the head. These muscles originate from the mastoid process of the cranium and insert into the medial border of each collarbone and the **sternum** (breastbone) at the base of the neck.

The Spinal Column

The spinal column, or **vertebral column**, is the central supporting structure of the body and is composed of 33 bones, each called a vertebra (7 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 4 coccygeal), and protects the spinal cord. The **vertebrae** are named according to the section of the spine in which they lie and are numbered from top to bottom (**FIGURE 7-23**). From the top down, the spine is divided into five sections:

- **Cervical spine.** The first seven vertebrae (C1 through C7) in the neck form the cervical spine. In addition to protecting the vital cervical spinal cord, the cervical spine supports the weight of the head and permits a high degree of mobility in multiple planes. The atlas (C1) and axis (C2) are uniquely suited to allow for rotational movement of the skull.
- **Thoracic spine.** The next 12 vertebrae (T1 through T12), in addition to the supporting muscles and ligaments found in the vertebral column, make up the thoracic spine. One pair of ribs is attached to each of the thoracic vertebrae and further stabilizes the thoracic spine. The spinous processes are slightly larger, reflecting their role as attachment points for muscles that hold the upper body erect and

FIGURE 7-23 The spinal column comprises 33 bones divided into five sections. Each vertebra is numbered and referred to by a letter corresponding to the section of the spine where it is located. For example, the fifth thoracic vertebra is referred to as T5.

© Jones & Bartlett Learning.

assist with the movement of the thoracic cavity during respiration.

- **Lumbar spine.** The next five vertebrae form the lumbar spine. These are the largest bones in the vertebral column and they are integral in carrying a large portion of the upper body weight. The lumbar spine is especially susceptible to injury because of this weight-bearing capacity.
- **Sacrum.** The sacrum is composed of five fused vertebrae that form the posterior plate of the pelvis. The sacrum is joined to the iliac bones of the pelvis with strong ligaments at the sacroiliac joints to form the pelvis.
- **Coccyx.** The last small three to five vertebrae, also fused together, form the coccyx, or tailbone. Coccyx injuries, although often extremely painful, are typically neurologically insignificant.

The first cervical vertebra (C1) is called the **atlas**. The atlas is located directly beneath the skull and provides support for the head. The atlas articulates with the occipital condyles at the base of the skull at the **atlanto-occipital joint**. The only motions of this joint are flexion and extension and lateral bending.

FIGURE 7-24 The cervical vertebrae.

© Jones & Bartlett Learning.

The second cervical vertebra (C2) is known as the **axis** and is the point at which the head rotates, such as when moving the head from left to right. A large offshoot of C2 is the dens, or odontoid process, which fits into the enlarged vertebral foramen of the atlas. The atlas rotates around the axis at the dens. The cervical vertebrae numbered C3 through C6 form the cervical curve. C7, called the vertebra prominens, is different. It has a large spinous process that may be seen and felt at the base of the neck (**FIGURE 7-24**).

The spinal cord is an extension of the brain, composed of virtually all the nerves that carry messages between the brain and the rest of the body. It exits through a large hole in the base of the skull called the foramen magnum and is contained within and protected by the vertebrae of the spinal column. The spinal column is virtually surrounded by muscles. However, the posterior spinous process of each vertebra can be felt as it lies just under the skin in the midline of the back.

The anterior part of each vertebra consists of a round, solid block of bone called the body. The posterior part of each vertebra forms a bony arch. This series of arches from one vertebra to the next forms a tunnel that runs the length of the spine called the spinal canal. The bones of the spinal canal encase and protect the spinal cord (**FIGURE 7-25**). Nerves branch from the spinal cord and exit from the spinal

FIGURE 7-25 The bones of the spinal column encase and protect the spinal cord. The vertebrae are shaped to accommodate space for the spinal cord and nerve roots, which pass through.

© Jones & Bartlett Learning.

canal between each two vertebrae to form the motor and sensory nerves of the body.

The vertebrae are connected by ligaments, and between each vertebra is a cushion called the intervertebral disk. These ligaments and disks allow some motion so the trunk can bend forward (flex) and back (extend), and they allow for rotation and lateral movement. However, they also limit motion of the vertebrae so that the spinal cord will not be injured. An injury to the spine may damage part of the spinal cord and its nerves that may not be protected by the vertebrae. Therefore, until the injury is stabilized, you must use extreme caution in caring for the patient to prevent injury to the spinal cord.

The Thorax

The thorax (chest) is formed by the 12 thoracic vertebrae (T1 through T12) and their 12 pairs of ribs. The boundaries of the thorax are the rib cage anteriorly, superiorly, and posteriorly and the diaphragm inferiorly.

Anteriorly, in the midline of the chest is the sternum. The superior border of the sternum forms the easily palpable jugular, or sternal, notch. This is the location where the trachea enters the chest. The sternum has three components: the manubrium, the body, and the xiphoid process. The upper section of the sternum is called the **manubrium**. The

FIGURE 7-26 Thoracic cavity.

© Jones & Bartlett Learning.

body comprises the rest of the sternum except for a narrow, cartilaginous tip inferiorly, which is called the **xiphoid process** (**FIGURE 7-26**).

Within the thoracic cage, the largest structures are the heart, lungs, and great vessels (**FIGURE 7-27**). The heart lies immediately behind the sternum (retrosternal). It extends from the second to the sixth ribs anteriorly and from the fifth to the eighth thoracic vertebrae posteriorly. The inferior border of the heart extends into the left side of the chest. Diseased hearts may be larger or smaller. The major blood vessels that travel to and from the heart also lie in the chest cavity. On the right side of the spinal column, the superior and inferior venae cavae carry blood to the heart.

Just beneath the manubrium of the sternum, the arch of the **aorta** (the body's largest artery) and the **pulmonary artery** exit the heart. The arch of the aorta passes to the left and lies along the left side of the spinal column as it descends into the abdomen. The **esophagus** lies behind the great vessels and directly on the anterior aspect of the spinal column as it passes through the chest into the abdominal cavity.

All space within the chest that is not occupied by the heart, great vessels, and esophagus is occupied by the lungs. Anteriorly, the lungs extend down to the surface of the diaphragm at the level of the xiphoid process. Posteriorly, the lungs extend farther inferiorly to the surface of the diaphragm at the level of the 12th thoracic vertebra.

FIGURE 7-27 The anterior aspect of the thorax shows the relative positions of the principal organs beneath the surface.

© Jones & Bartlett Learning.

The Appendicular Skeleton

The appendicular skeleton includes the bones of the shoulder and pelvic girdles, the upper extremities (arms [more commonly thought of as the upper arms], forearms, wrist, hands, and fingers), and the lower extremities (thighs, legs, ankles, instep, and toes).

The Shoulder Girdle

The **shoulder girdle** attaches the upper extremity to the body at the glenohumeral joint. The two major components of the shoulder girdle are the **scapula** (shoulder blade) and the **clavicle** (collarbone). The scapula is a flat, triangular bone held to the rib cage posteriorly by powerful muscles that buffer it against injury.

The clavicle is a slender, S-shaped bone that is easily felt on either side of the sternal notch. The lateral end of the clavicle articulates with the acromion and the medial end with the manubrium.

FIGURE 7-28 **A.** Anterior view of the shoulder girdle, including the clavicle. **B.** Posterior view of the shoulder girdle, including the scapula.

© Jones & Bartlett Learning.

The raised tip of the scapula is called the **acromion process**. It protects the shoulder joint and provides a site of attachment for both the clavicle and various shoulder muscles (**FIGURE 7-28A**). Important muscles of the shoulder, including those of the rotator cuff, originate here.

The Shoulder Joint

The shoulder joint is a ball-and-socket joint in which the head of the humerus articulates with the **glenoid fossa**, which is part of the scapula (**FIGURE 7-28B**). The hip and shoulder are typical ball-and-socket joints.

Four ligaments attach the humeral head to the glenoid fossa. A fibrocartilage ring surrounds the glenoid rim and provides a point of attachment for the capsule, which is made up of fibrous connective

tissue. A **bursa** is a padlike sac situated between a tendon and a bone that cushions and protects joints such as the shoulder, hip, or knee. It may be lined with a synovial membrane and typically contains fluid that helps reduce the amount of friction between a tendon and a bone or between a tendon and a ligament. Examples include the olecranon bursa of the elbow and the prepatellar bursa of the knee. Bursitis is inflammation of a bursa.

Words of Wisdom

Acromioclavicular (AC) separation, also called a separated shoulder, occurs when any of the four ligaments of the AC joint are partially or completely torn. In partial tears, no deformity is noted unless the patient attempts to hold a weight with the arm directed downward. In this case, the weakened joint is transiently widened, a finding visible on radiographs. In patients with complete separation, in which all four ligaments are severely damaged, the clavicle essentially lies above the acromion, causing a visible deformity in the patient's shoulder area.

The Upper Extremity

The upper extremity consists of the arm (commonly described as the upper arm), forearm, wrist, hand, and fingers.

The **humerus** is the bone of the upper arm (**FIGURE 7-29**). It articulates proximally with the glenoid fossa and distally with the radius and ulna at the elbow joint. The elbow joint is a hinge joint, permitting motion in one plane only. Several ligaments connect the humerus, radius, and ulna at the elbow joint, and a fluid-filled bursa cushions and protects the joint posteriorly.

The Forearm and Wrist

The forearm extends from the elbow to the wrist. The forearm contains two bones, the **radius** and **ulna**. The radius is the larger of the two bones and is located on the lateral side (the thumb side) of the forearm when the forearm is in the anatomic position, and the ulna is narrow and located on the little finger side. It serves as the pivot around which the radius turns at the wrist to rotate the palm upward (supination) or downward (pronation). The proximal portion of the radius is called the radial

FIGURE 7-29 The (upper) arm contains the humerus; the forearm contains the radius and ulna.

© Jones & Bartlett Learning.

head. The distal portion contains a small bony protrusion, the styloid process, to which ligaments of the wrist are attached.

The wrist is made of a group of eight irregularly shaped bones, called the carpals. The carpals include the triquetrum, pisiform, capitate, lunate, hamate, trapezoid, trapezium, and scaphoid (carpal navicular) bones. The carpal tunnel is formed by the space bounded by the trapezium and hamate dorsally and the flexor retinaculum, a sheath of tough connective tissue that forms the roof of the carpal tunnel, on the palmar side. Tendons, nerves, and blood vessels lie within the carpal tunnel. Structures within the carpal tunnel include the long flexor tendons to the fingers and the median nerve, which supplies sensory and motor function to the radial half of the palm of the hand.

The Hand

The **metacarpal bones** are the bones that form the hand. The **phalanges** (singularly called a phalanx) are a series of small bones that exist in each finger. The phalanges in the fingers form hinge joints. Each finger has three phalanges, except the thumb, which has only two (**FIGURE 7-30**). The **carpometacarpal joint** of the thumb is a **saddle joint**, consisting of two saddle-shaped articulating surfaces that are

FIGURE 7-30 The principal bones in the wrist and hand include the carpals, the metacarpals, and the phalanges.

© Jones & Bartlett Learning.

oriented at right angles to one another so that the complementary surfaces articulate with each other. Movement in these joints can occur in two planes. Arthritis commonly affects the carpometacarpal joint, resulting in stiffness and deformity.

The Pelvic Girdle

The **pelvis**, or pelvic girdle, is where the lower extremity attaches to the body (**FIGURE 7-31**). The pelvis contains a ring of bones formed by the sacrum and the coxal, or pelvic, bones; the sacrum is posterior and the coxal bones are on each side. Each coxa consists of three fused bones: the **ilium**, **ischium**, and **pubis**. The pelvis contains three joints: the two posterior **sacroiliac joints** and the interior midline **pubic symphysis**. The location where the ilium connects with the sacrum is the sacroiliac joint. The pubic symphysis is the lower midportion of the pelvic ring where the left and right sides fuse together. The superior portion of the ilium is the iliac crest. The obturator foramen is an opening between the ischium and pubis that contains several important nerves and muscles. The pelvic girdle supports the body weight and protects the internal organs. In a pregnant woman, the bones protect the developing fetus and provide a passageway through which the infant passes during delivery.

FIGURE 7-31 The pelvis is a closed bony ring that consists of the sacrum, ilium, ischium, pubis, acetabulum, and pubic symphysis.

© Jones & Bartlett Learning.

Words of Wisdom

Pay attention to spelling to prevent misunderstandings. Although *ilium* and *ileum* are pronounced the same, they refer to two different parts of the body.

- Ilium = the bony prominences of the pelvis
- Ileum = the lower three-fifths of the small intestine

The Lower Extremity

The lower extremity is made of the hip, thigh, knee, leg, ankle, foot, and toes (**FIGURE 7-32**). The **acetabulum** is the socket of the ball-and-socket joint that connects the pelvic girdle with the lower extremity. The thigh is the part of the lower extremity that extends from the hip to the knee and contains the **femur**, which is the longest and strongest bone in the body. The uppermost portion of the femur, the **femoral head**, articulates with the pelvic girdle at the acetabulum. In addition to the femoral head, the proximal femur consists of the neck, **greater trochanter** (upper part of the femur), and lesser trochanter (lower part of the femur). The greater trochanter arises lateral to the juncture of

FIGURE 7-32 The principal parts of the lower extremity, including the femur, femoral head, greater and lesser trochanters, patella, tibia, and fibula.

© Jones & Bartlett Learning.

the neck and shaft and is part of the femur. Several ligaments and tendons provide integrity to the hip joint. The articular capsule is supported by three ligaments that are quite strong; they support much of the body's weight.

The Leg

At the distal end of the femur, the lateral and medial condyles articulate with the proximal tibia at the knee (**FIGURE 7-33**). These are important sites of muscle and ligament attachment. The **patella**, or kneecap, lies within the major anterior tendon of the thigh muscles and articulates with the femur.

The leg is made of the tibia and fibula, and extends from the knee to the ankle. The **tibia** is the longer and thicker of the two bones and is situated on the anterior surface of the leg. The anterior portion of the tibia, covered only by skin, is commonly called the shin. The flat medial and lateral condyles of the proximal tibia articulate with the femoral

**FIGURE 7-33** The femur.

© Jones & Bartlett Learning.

condyles at the knee. The **medial malleolus**, which forms the medial side of the ankle joint, lies at the distal end of the tibia.

The second of the two leg bones, the **fibula**, runs behind and beside the tibia. It does not articulate directly with the femur, but rather with the tibia at the head. An enlargement of the distal end of the fibula forms the lateral wall of the ankle joint, the **lateral malleolus**.

The Knee

The knee joint is traditionally classified as a hinge joint and is unusual because it contains ligaments within the joint. Thick crescent-shaped articular disks, menisci, cover the margins of the tibia to cushion the articular surface. The anterior cruciate ligament, which extends between the tibia and femur, prevents abnormal anterior movement (**hyperextension**) of the tibia. The posterior cruciate

**A****B****FIGURE 7-34** A. Anterior view of the knee. B. Posterior view of the knee.

© Jones & Bartlett Learning.

ligament prevents abnormal posterior displacement of the tibia. Several tendons, as well as collateral ligaments, lend additional strength to the knee joint. The knee is surrounded by several fluid-filled bursae (**FIGURE 7-34**).

The Ankle

The talus articulates with the tibia and fibula to form the ankle (**FIGURE 7-35**). The calcaneus, or heel

FIGURE 7-35 **A.** The surface landmarks of the foot, including the talus, the calcaneus, and the phalanges. **B.** Soft tissue of the ankle.

© Jones & Bartlett Learning.

bone, lies inferior and lateral to the talus, providing additional support. A fibrous capsule surrounds the ankle joint; the medial and lateral portions are thickened to form ligaments. Movements include dorsiflexion and plantar flexion, as well as limited inversion and eversion.

The metatarsals and phalanges of the foot are arranged similarly to the bones of the hand. The toes have three phalanges each, except the big toe, which has two phalanges. The ball of the foot is the junction between the metatarsals and the phalanges.

The Skeletal System: Physiology

The skeletal system is responsible for several functions. Bones protect internal organs and, with muscles, enable movement. Bone also serves as a storage site for minerals, particularly calcium, and has a role in the formation of blood cells and platelets. Calcium is the main element the various bone cells use to create a structure that is hard and

Special Populations

Hip fractures are actually fractures of the proximal portion of the femur near or at the site of articulation with the acetabulum. These fractures are classified based on the structures of the femur involved (**FIGURE 7-36**).

Dislocations of the hip joint commonly occur from a fall or during a motor vehicle crash in which the knee impacts the dashboard. The force of the impact is transmitted posteriorly to the hip, resulting in posterior dislocation. Anterior hip dislocations are less common.

FIGURE 7-36 Fractures of the hip.

© Jones & Bartlett Learning.

resilient. Bones store and release calcium, which is important for other body systems.

Bones consist of collagen and the mineral hydroxyapatite, a compound that contains calcium and phosphate. The collagen fibers in bone act much like reinforcing rods in a concrete structure, lending flexibility and strength to the bone. The mineral components of the bone supply strength for bearing weight, much like concrete does in a structure. Bone without the necessary amount of mineral is excessively flexible; bone without enough collagen is extremely brittle.

The skeletal system also helps with the creation of various types of blood cells. In the marrow of certain types of bones, special cells are present that can transform themselves into RBCs, WBCs, and platelets. The cells, when stimulated, help replace worn out cells in the blood.

Bone is a living substance with cells requiring a blood supply. During a person's life, bones are constantly remodeled to meet the stresses that are placed on them. The level of a person's activity directly affects how the bones are remodeled.

Words of Wisdom

As you gain a better understanding of the anatomy and physiology of the body, it is important to remember that body systems work together and not in isolation. A person who falls and breaks a leg has an isolated injury. It may appear to you that the skeletal system is the only system that is involved. But then ask yourself the following questions: Is there bleeding inside the leg? Is there damage to the nerves, tendons, or ligaments? Has the injury broken the skin and is there now a risk of infection? A seemingly simple illness or injury can involve several body systems. Give each patient a thorough assessment.

The Musculoskeletal System

Skeletal Component

The human body is a well-designed system whose form, upright posture, and movement are provided by the **musculoskeletal system**. The term *musculoskeletal* refers to the bones and voluntary muscles of the body. The musculoskeletal system also protects the vital internal organs of the body. Muscles are a form of tissue that allows body movement. There are more than 600 muscles in the musculoskeletal system. The type of muscle found here is called skeletal muscle. Other types of muscle outside of the musculoskeletal system include smooth muscle (**involuntary muscle**) and cardiac muscle.

Smooth muscle is found within blood vessels, bronchi, the intestines, and other places. Smooth muscle responds only to primitive stimuli such as stretching, heat, or the need to relieve waste. A person cannot exert any voluntary control over this type of muscle. For example, when you hear your stomach growling, you really are hearing the

FIGURE 7-37 The three types of muscle are skeletal, smooth, and cardiac.

© Jones & Bartlett Learning.

rhythmic contractions of the smooth muscles of your intestines.

Cardiac muscle contributes to the functioning of the cardiovascular system and is found only within the heart (**FIGURE 7-37**). The heart is a large muscle composed of a pair of pumps of unequal force: one of lower pressure and one of higher pressure. The heart must function continuously from birth to death. It is a specifically adapted involuntary muscle with a rich blood supply and its own electrical system, which makes it different from both skeletal and smooth muscle. Another difference is that cardiac muscle has the property of “automaticity,” which means that the heart muscle can generate and conduct electricity without influence from the brain. This property is unique to heart muscle. Cardiac muscle can tolerate an interruption of its blood supply for only a few seconds. It requires a continuous supply of oxygen and glucose for normal function. Because of its special structure and function, cardiac muscle is placed in a separate category.

Skeletal muscle includes all muscles attached to the skeleton. It forms the bulk of the tissue of the arms and legs, and the major muscle mass of the body. It is also called **striated muscle**, because striations can be seen in it during microscopic examination, or **voluntary muscle**, because all skeletal muscle is under direct voluntary control of the brain and can be stimulated to contract or relax at will. Movement of the body, like waving or walking, results from skeletal muscle contraction or relaxation. Usually, a specific motion is the result of several muscles contracting and relaxing simultaneously.

Skeletal muscle varies greatly in size and shape, from thin strands to the large muscles of the thigh and back. It is also found along the spine and buttocks, and comprises the muscles of the tongue, soft palate, scalp, pharynx, upper esophagus, and eye. Approximately 40% to 50% of normal body weight is skeletal muscle because of its high water content.

Skeletal muscles are profoundly affected by the amount of training and work to which they are subjected. Unused muscles tend to **atrophy** (shrink or waste away), whereas physical training promotes **hypertrophy** (increase in size).

Most muscles within the body operate on the principle of antagonistic pairs. The muscles of the upper arm include the **biceps** muscle, which is located on the anterior aspect of the humerus. This muscle moves the lower part of the arm toward the head. If the muscle were working alone, the person would have little control over the speed of that movement. The way the body achieves control and fine movement is to have the biceps compete against another muscle group. The biceps competes with the **triceps** muscle. Without the triceps, you would slap yourself in the face every time you bend your arm. The biceps works to slow the movement of the triceps as the arm is extended.

There are some important muscle groups to know. **FIGURE 7-38** and **TABLE 7-4** show the major muscles, their locations, and their functions.

Muscular Component

The musculoskeletal system has several functions. A person's ability to move and to manipulate the environment is made possible by the contraction and relaxation of this system. A by-product of this movement is heat. When you get cold, you involuntarily shake your muscles, or shiver, to produce heat.

Shivering is an essential function. Another function of muscles is to protect the structures under them, such as the intestines, which are protected by the rectus abdominis muscles.

Energy Sources

Muscular contraction requires an energy source—ATP—and continues as long as a certain neurotransmitter, acetylcholine, is released. Muscle fibers have just enough ATP for short-term contraction. ATP must be regenerated when fibers are active, using existing ATP molecules in the cells. ATP is regenerated from adenosine diphosphate (ADP) and phosphate. Creatine phosphate is an organic compound in muscle tissue that can store and provide energy for muscle contraction with high-energy phosphate bonds. Creatine phosphate is four to six times more abundant in muscle fibers than ATP; however, it does not directly supply energy. Rather, it stores excess energy from the mitochondria in the phosphate bonds.

When ATP breaks down, energy from creatine phosphate is transferred to ADP molecules to convert them back into ATP. Creatine phosphate stores are exhausted rapidly when muscles are active; therefore, the muscles use cellular respiration of glucose as energy to synthesize ATP.

Oxygen Use and Debt

Oxygen is required for the breakdown of glucose in the mitochondria. RBCs carry oxygen bound to hemoglobin molecules. **Hemoglobin** is the pigment that makes blood appear red. One hemoglobin molecule reversibly binds with four oxygen molecules. The pigment **myoglobin** is synthesized in the muscles and gives skeletal muscles their red-brown color. Myoglobin can also combine with oxygen and temporarily store it to reduce muscular requirements for continuous blood supply during contraction.

When skeletal muscles are used for 1 minute or longer, anaerobic respiration is required for energy. In one type of anaerobic respiration, glucose is broken down via glycolysis to yield pyruvic acid, which reacts by producing lactic acid. Recall that **lactic acid** can accumulate in muscles but diffuses in the bloodstream, reaching the liver, where it is synthesized into glucose.

When a person exercises strenuously, oxygen is used mostly to synthesize ATP. As lactic acid

FIGURE 7-38 The major muscle groups.

TABLE 7-4 Muscles: Locations and Functions		
Name of Muscle	Location	Function
Biceps	Anterior, humerus	Flexes lower arm
Triceps	Posterior, humerus	Extends lower arm
Pectoralis	Anterior, thorax	Flexes and rotates arm
Latissimus dorsi	Posterior, thorax	Extends and rotates arm
Rectus abdominis	Anterior, abdomen	Flexes and rotates spine
Tibialis anterior	Anterior, tibia	Flexes foot toward head
Gastrocnemius	Posterior, tibia	Points foot away from head
Quadriceps (four separate muscles)	Anterior, femur	Extends lower leg
Biceps femoris	Posterior, femur	Flexes lower leg
Gluteus (three separate muscles)	Posterior, pelvis	Extends and rotates leg

TABLE 7-5 Changes in Muscular Metabolism

Type of Exercise	Pathway Needed	Production of ATP	Result
Low to moderate intensity: blood flow provides enough oxygen for the needs of the cell	Glycolysis, which results in formation of pyruvic acid and aerobic respiration	For skeletal muscle, 36 molecules of ATP per glucose	Exhalation of carbon dioxide
High intensity: oxygen supply is not enough for the needs of the cell	Glycolysis, which results in formation of lactic acid	Two molecules of ATP per glucose	Buildup of lactic acid

Abbreviation: ATP, adenosine triphosphate

© Jones & Bartlett Learning.

increases, an oxygen debt develops. Oxygen debt is equivalent to the amount of oxygen that liver cells require to convert the lactic acid into glucose, as well as the amount needed by muscle cells to restore ATP and creatine phosphate levels.

The sensation of muscle fatigue occurs when the energy supply to the muscle is inadequate to meet the energy demands. If muscle fatigue occurs as a result of excessive muscular activity, rest produces quick recovery. If it occurs from a lack of oxygen or essential nutrients or electrolytes (such as sodium or calcium), however, rest will not result in such a quick recovery.

It may take several hours for the body to convert lactic acid back into glucose. Muscles may experience a change in their metabolic activity as exercise levels change. Increased exercise raises the capacity of the muscles for glycolysis. Aerobic exercise increases the capacity of the muscles for aerobic respiration. This process is summarized in **TABLE 7-5**.

The Respiratory System: Anatomy

The **respiratory system** consists of all the structures of the body that contribute to respiration, or the process of breathing (**FIGURE 7-39**). It includes the nose, mouth, throat, larynx, trachea, bronchi, and bronchioles, which are all air passages or airways. The system also includes the lungs, where oxygen passes into the blood and carbon dioxide escapes. Finally, the respiratory system includes the diaphragm, the muscles of the chest wall, and accessory muscles of breathing, which permit normal respiratory movement. In this text, the term *airway* usually refers to the upper airway or the passage above the larynx (voice box).

Safety

A cough is the perfect mechanism for aerosolizing infectious materials. Whenever possible, minimize the risk of exposure by placing an oxygen mask or a simple face mask on a patient with a cough.

The Upper Airway

The structures of the upper airway are located anteriorly and at the midline. The upper airway includes the nose, mouth, tongue, jaw, oral cavity, larynx, and pharynx.

The tongue is a large muscle attached at the mandible and hyoid bone. The hyoid bone is a small bone located between the chin and the mandibular angle. The jaw, tongue, epiglottis, and thyroid cartilage attach at this point. The palate forms the roof of the mouth and separates the oropharynx and nasopharynx. The anterior portion is the hard palate, and the posterior portion, beyond the teeth, is the soft palate. The adenoids are located on the posterior nasopharyngeal wall. Adenoids are lymph tissues that filter bacteria and viruses.

The lateral borders of the glottis are the vocal cords, which are white bands of tough, fibrous tissue. Voice is generated by air passing through the vibrating vocal cords. The arytenoid cartilage is a pyramidlike cartilaginous structure that forms the posterior attachment of the vocal cords. The pyramiform fossae are hollow pockets along the lateral borders of the larynx.

The larynx is typically considered the dividing line between the upper and lower airway. The larynx is a rather complex arrangement of tiny bones, cartilage, muscles, and two vocal cords. The larynx

FIGURE 7-39 The respiratory system consists of all structures of the body that contribute to the process of breathing.

© Jones & Bartlett Learning.

does not tolerate any foreign solid or liquid material. A violent episode of coughing and spasm of the vocal cords will result from contact with solids or liquids. The nose and mouth lead to the oropharynx, the upper part of the throat that lies at the back of the mouth, behind the oral cavity. The pharynx comprises the nasopharynx, oropharynx, and the laryngopharynx. The nostrils lead to the **nasopharynx** (above the roof of the mouth, or soft palate), and the mouth leads to the oropharynx. The nasopharynx and the nasal passages, which include the turbinates (three curved bone shelves inside each nasal passage that force inhaled air to flow in a steady pattern across the largest possible surface of the cilia and tissue), warm, filter, and humidify air as a person breathes. The nasal mucosa is the mucous membrane that lines the nasal cavity. Olfactory receptors located in the epithelium in the nasal cavity are responsible for recognizing odors.

Air enters through the mouth more rapidly and directly. As a result, it is less moist than air that enters through the nose.

Two passageways are located at the bottom of the pharynx: the esophagus behind and the trachea (windpipe) in front. The trachea is a tubular structure approximately 10 to 12 cm in length and consists of C-shaped cartilaginous rings. Air enters the trachea and goes to the lungs. Food and liquids enter the pharynx and pass into the esophagus, which carries them to the stomach.

Protecting the opening of the trachea is a thin, leaf-shaped valve called the **epiglottis**. This valve allows air to pass into the trachea but prevents food and liquid from entering the airway under normal circumstances. Air moves past the epiglottis into the larynx and the trachea. The glottis or glottic opening is the space between the vocal cords where air enters the trachea.

The shield-shaped thyroid cartilage is the major laryngeal structure and is formed by two plates that join in a “V” shape anteriorly to form the laryngeal prominence known as the Adam’s apple. This is easily seen in the middle of the front of the neck. The thyroid cartilage is actually the anterior part of the larynx. Tiny muscles open and close the vocal cords and control tension on them. Sounds are created as air is forced past the vocal cords, making them vibrate. These vibrations make the sound. The pitch of the sound changes as the cords open and close. You can feel the vibrations if you place your fingers lightly on the larynx as you speak or sing. The vibrations of air are shaped by the tongue and muscles of the mouth to form understandable sounds. The posterior portion is made of smooth muscle. The thyroid cartilage is suspended from the hyoid bone by the thyroid ligament.

The Lower Airway

The lower airway contains the trachea, bronchial tree, alveoli, and lungs. The lower airway is where

Words of Wisdom

Asthma is a recurring condition of reversible acute air-flow obstruction in the lower airway. It is the most common chronic disease of childhood. Four distinct events occur in an asthma attack. First, a muscle spasm occurs when the smooth muscle layers around the airways constrict (**bronchospasm**), resulting in narrowing of the airway diameter. Second, increased secretion of mucus causes a mucus plug, further decreasing the airway diameter. Third, inflammatory cell proliferation causes swelling of the lining of the airways, also decreasing airway diameter. Finally, WBCs accumulate in the airway and secrete substances that worsen the muscle spasm and increase mucus production.

The most common cause of an asthma attack is an upper respiratory infection, such as bronchitis or a cold. Other causes include changes in environmental conditions; emotions, especially stress; allergic reactions to pollens, foods (chocolate, shellfish, milk, nuts), or drugs (penicillin, local anesthetics); and occupational exposures.

The severity of asthma attacks varies among patients. In severe cases (status asthmaticus), the patient may die as a result of respiratory failure. In other cases, treatment may produce rapid improvement and resolution of the asthmatic crisis.

gas exchange occurs; oxygen diffuses into the pulmonary capillaries and carbon dioxide diffuses in the opposite direction.

As mentioned earlier, immediately below the thyroid cartilage is the palpable cricoid cartilage. The inferior aspect of the thyroid cartilage articulates with the cricoid cartilage or cricoid ring. The cricoid cartilage is the only upper airway structure that forms a complete ring. It is the first tracheal ring and is completely cartilaginous. The anterior portion of the cricoid ring is the narrowest and is separated from the thyroid cartilage by the cricothyroid membrane—a thin, fibrous membrane located between the cricoid ring and the thyroid cartilage. The cricothyroid membrane can be felt as a depression in the midline of the neck just inferior to the thyroid cartilage.

Below the cricoid cartilage is the trachea. The trachea is approximately 5 inches (13 cm) long and is a semirigid, enclosed air tube made up of rings of cartilage that are open in the back. This enables food to pass through the esophagus, which lies right behind the trachea. The rings of cartilage keep the trachea from collapsing when air moves into and out of the lungs.

At the level of the fifth thoracic vertebra, the trachea branches into the right and left main stem bronchi at the carina, a projection of the lowest portion of the tracheal cartilage.

Beyond the carina, air enters the lungs through the right and left **main stem bronchi**. The point of entry for the bronchi, blood vessels, and nerves into each lung is called the **hilum**. The main stem bronchi divide into the smaller **secondary bronchi**, each one going to a separate lobe of the lung (**FIGURE 7-40**).

Secondary bronchi branch into the even smaller **tertiary bronchi**, which continue to branch several times. After several generations of successive branching, **bronchioles**, extremely small subdivisions of the bronchi, are formed. Each bronchiole divides to form **alveolar ducts**. Each alveolar duct ends in clusters known as **alveoli**, tiny sacs of lung tissue in which gas exchange takes place. Pulmonary **surfactant** found in the alveoli reduces surface tension to increase pulmonary compliance, allowing the alveoli to fully expand, and prevent atelectasis (alveolar collapse) at the end of expiration. The lung contains approximately 300 million alveoli; each alveolus is approximately 0.01 inch (0.33 mm) in diameter. Capillaries cover the alveoli.

FIGURE 7-40 The main stem bronchi and related structures.

© Jones & Bartlett Learning.

The **pulmonary-capillary membrane** (also called the alveolocapillary membrane) lies between the alveolus and the capillary and is extremely thin, consisting of only one cell layer. Respiratory exchange between the lung and blood vessels occurs in the alveoli at the pulmonary-capillary membrane.

Lungs

The **lungs** are the primary organs of breathing. The right lung contains three lobes (the upper, middle, and lower lobes); the left lung contains only two (the upper and lower lobes). The lungs are surrounded by a membrane of connective tissue known as **pleura**. Another pleural membrane lines the inner borders of the rib cage, or **pleural cavity**.

The connective tissue, small airways, and alveoli are collectively referred to as the lung parenchyma. The lung parenchyma is composed of two lobes on the left and three lobes on the right. It is surrounded by the pleurae, or pleural membranes. The pleural membrane that lines the pleural cavity is the **parietal pleura**. The parietal pleura covers the thoracic wall and superior face of the diaphragm. The pleural membrane that covers the external surface of the lungs is referred to as the **visceral pleura**. The pleurae produce a pleural or serous lubricating

Special Populations

The anatomy of the respiratory system in children is proportionally smaller and less rigid than that in adults (**FIGURE 7-41**). A child's nose and mouth are much smaller than those of an adult. The larynx, cricoid cartilage, and trachea are smaller, softer, and more flexible as well. This makes the mechanics of breathing much more delicate. A child's pharynx is also smaller and less deeply curved. The tongue takes up proportionally more space in a child's mouth than in an adult's mouth.

These anatomic differences are important for your assessment. For example, the smaller larynx of a child becomes obstructed more easily. The chest wall in children is softer. Therefore, children depend more heavily on the diaphragm for breathing. You will notice that the abdomen moves in and out considerably with each breath, especially in an infant. Young infants do not know how to breathe through the mouth. Therefore, as you assess an infant or a child, you must carefully consider these differences.

FIGURE 7-41 The respiratory system of a child is proportionally smaller and less rigid than that of an adult.

fluid that allows the lungs to glide easily over the intrathoracic wall during breathing. Both layers of pleura work together to help maintain normal expansion and contraction of the lung.

A potential space known as the **pleural space** exists between the visceral and parietal pleural layers. Normally, the two membranes are close together

and an actual space does not exist. Under certain disease conditions or following trauma, blood, excess pleural fluid, pus, and/or air may accumulate in the pleural space, potentially causing respiratory problems (FIGURE 7-42).

The lungs receive blood in two ways. Deoxygenated blood flows from the right ventricle via the pulmonary arteries. This blood flows through pulmonary capillaries, is reoxygenated at the alveoli, and then returns to the left side of the heart via the pulmonary veins. In addition, bronchial arteries branch off of the thoracic aorta and supply the lung tissues themselves with blood. Deoxygenated blood returns to the heart via the bronchial veins. Peripherally in the lungs, venous blood from the bronchi enters the pulmonary veins, returning with oxygenated blood from the alveoli.

Muscles of Breathing

There are several muscles involved in making the lungs expand and contract. The primary muscle is called the **diaphragm**. Contraction of the diaphragm, along with that of the chest wall muscles, allows air to be drawn into the lungs. Anteriorly, it attaches to the costal arch; posteriorly, it attaches to the lumbar vertebrae. The diaphragm cannot

FIGURE 7-42 The pleural layers lining the chest wall and covering the lungs are an essential part of the breathing mechanism. The pleural space is not an actual space until blood or air leaks into it, causing the pleural surfaces to separate.

be seen or palpated without opening the chest or abdomen.

The diaphragm is unique because it has characteristics of voluntary (skeletal) and involuntary

YOU are the Provider

Part 2

As you approach the patient, a police officer stops you and states that the patient was an innocent bystander in an apparent drive-by shooting. Officers have searched the scene and have found no other patients. Your patient presents as alert and oriented, and in a substantial amount of pain. He states that he heard five or six gunshots; but he is unsure of how many times he was hit. You direct your partner to manually stabilize the neck as you roll the patient onto his back. As you remove the blood-soaked shirt, you find three gunshot wounds: one in his left chest, one on his left arm, and one to his left upper abdominal quadrant. His chief complaint is that it is becoming increasingly difficult to breathe and that it feels like his stomach is on fire.

Recording Time: 1 Minute

Appearance	Severe pain
Level of consciousness	Alert and oriented
Airway	Patent
Breathing	12 breaths/min, shallow
Circulation	Cool, pale, and clammy

- What are the components of the respiratory system?
- On the basis of your knowledge of anatomy, what possible organs may be damaged as a result of the gunshot wound to the abdomen?

FIGURE 7-43 The dome-shaped diaphragm divides the thorax from the abdomen. It is pierced by the great vessels and the esophagus.

© Jones & Bartlett Learning.

(smooth) muscle. It is a dome-shaped muscle that divides the thorax from the abdomen and is pierced by the great vessels and the esophagus (**FIGURE 7-43**). It acts like a voluntary muscle when you take a deep breath, cough, or hold your breath. You control these variations in the way you breathe.

However, unlike other skeletal or voluntary muscles, the diaphragm performs an automatic function. Breathing continues during sleep and at all other times. Although you can hold your breath or temporarily breathe faster or slower, you cannot continue these variations in the breathing pattern indefinitely. When the concentration of carbon dioxide becomes too high, automatic regulation of breathing resumes. Therefore, although the diaphragm looks like voluntary skeletal muscle and is attached to the skeleton, it behaves, for the most part, like an involuntary muscle.

The other muscles involved in breathing are the intercostal muscles, the abdominal muscles, and the pectoral muscles. Muscles of the chest wall are innervated by the intercostal nerves, causing them to expand and contract, along with the diaphragm, to facilitate breathing. During inhalation, the diaphragm and intercostal muscles contract. When the diaphragm contracts, it moves down slightly, enlarging the thoracic cage from top to bottom. When the intercostal muscles contract, they move the ribs

up and out. These actions combine to enlarge the chest cavity in all dimensions. Pressure in the thoracic cavity then falls, making it lower than atmospheric pressure, causing air to flow into the lungs. This is referred to as negative pressure breathing because air is essentially sucked into the lungs. This part of the cycle is active, requiring the muscles to contract.

Street Smarts

When providing positive-pressure ventilation via bag-mask device, the lungs are expanding due to the forced air when the bag is squeezed. Once the bag is released, air flows out passively because there is a greater pressure inside the thoracic cavity. This process is different from the pressure gradient created as the muscles contract and create a negative pressure inside the chest, which is an active process.

Words of Wisdom

Each intercostal muscle is made up of a muscle group (muscle layers) that works together to move the ribs and facilitate breathing.

- External intercostal muscles are the inspiratory breathing muscles. They help move the ribs up and out during inhalation.
- Internal intercostal muscles are the expiratory breathing muscles. They pull the ribs down and in during forced exhalation.
- Innermost intercostal muscles are deep to the plane of the internal and external intercostal muscles and work in conjunction with internal intercostal muscles during exhalation.

During exhalation, the diaphragm and the intercostal muscles relax. Unlike inhalation, exhalation does not normally require muscular effort. As these muscles relax, all dimensions of the thorax decrease, and the ribs and muscles assume a normal resting position. When the volume of the thoracic cavity decreases, air in the lungs is compressed into a smaller space and pressure is greater than atmospheric pressure. Intrapulmonary pressure is increased, and air is pushed out through the trachea. This phase of the cycle is passive.

The process of breathing is typically easy and requires little muscular effort. But, now imagine

breathing through a straw and suddenly the diameter of the straw decreases. The smaller the diameter of the straw, the more effort you will now have to exert to move air. As the resistance in the airway increases, you will begin to use more muscle groups, namely your abdominal and pectoral muscles, to assist the diaphragm in moving that air.

Chronic bronchitis results from overgrowth of the airway mucous glands and excess secretion of mucus, which blocks the airway. Patients have a chronic productive cough. Emphysema results from destruction of the alveolar walls, which creates resistance to expiratory airflow. The major cause of chronic obstructive pulmonary disease (COPD) is cigarette smoking.¹ Industrial inhalants (such as asbestos and coal dust), air pollution, and tuberculosis also can result in COPD. The patient who is experiencing an acute COPD episode will report shortness of breath with gradually increasing symptoms over a period of days. This concept is discussed in greater detail in Chapter 17, *Respiratory Emergencies*.

Words of Wisdom

Chronic obstructive pulmonary disease (COPD) is a progressive, irreversible disease of the airway marked by decreased inspiratory and expiratory capacity of the lungs. COPD may result from chronic bronchitis (excess mucus production) or emphysema (lung tissue damage with loss of elastic recoil of the lungs). Patients with COPD usually have a combination of both problems and generally function at a certain baseline level until an event occurs that causes an acute episode.

The Respiratory System: Physiology

The primary function of the respiratory system is to exchange gases at the pulmonary-capillary membrane, or to conduct **respiration**. Oxygen is essential for the body to function. The amount of oxygen in inspired air is approximately 21%. The blood does not use all inhaled oxygen as it passes through the body. Exhaled air contains 16% oxygen and 3% to 5% carbon dioxide; the rest is nitrogen. This 16% concentration of oxygen is adequate to support artificial ventilation. **Ventilation** is the process of moving air in and out of the lungs. Therefore, as you provide

mouth-to-mouth artificial ventilations to a patient who is not breathing, the patient is receiving a 16% concentration of oxygen with each ventilation.

Respiration

At the pulmonary-capillary exchange surface, the alveolus and the RBC are very close. Diffusion is the process by which a gas dissolves in a liquid. Through the process of diffusion, the gases move from a higher concentration to a lower concentration. Therefore, oxygen moves across the membrane into the capillaries, where it attaches to the hemoglobin. Likewise, carbon dioxide moves from the bloodstream into the alveoli, where the concentration is lower. Oxygenated blood enters the left side of the heart and is pumped to the tissues. Oxygen is “offloaded” from the RBCs to the tissues as carbon dioxide and waste products from the tissues are “loaded” into the bloodstream. Venous blood returns to the right side of the heart and the pulmonary capillary bed (via the pulmonary arteries). The carbon dioxide diffuses into the alveoli and is released into the atmosphere as the person exhales (**FIGURE 7-44**). The primary waste product of metabolism is carbon dioxide, which is carried in the blood to the lungs.

Because there are so many alveoli, a fairly large surface area exists for respiratory exchange to occur in the context of the relatively limited size of the thoracic cavity. The total surface area created around the alveoli is more than 85 m². This is substantially more than would exist if each lung consisted of only a single sphere, like a large balloon. In that case, the surface area would be only 0.01 m² (1 m = 39.37 inches).

The Chemical Control of Breathing

The brain—or more specifically, the respiratory center in the brainstem—controls breathing. This area is in one of the best-protected parts of the nervous system—deep within the skull. The nerves in this area act as sensors for the level of carbon dioxide in the blood and subsequently the spinal fluid. The brain automatically controls breathing if the level of carbon dioxide or oxygen in the arterial blood is too high or too low. In fact, adjustments can be made in just one breath. For these reasons, you cannot hold your breath indefinitely or breathe rapidly and deeply indefinitely.

FIGURE 7-44 In the capillaries of the lungs, oxygen (O_2) passes from the blood to the tissue cells, and carbon dioxide (CO_2) and waste pass from the tissue cells to the blood.

© Jones & Bartlett Learning.

Words of Wisdom

Measurements of oxygen and carbon dioxide levels in the blood are called the **partial pressure of oxygen (P_{aO_2})** and the **partial pressure of carbon dioxide (P_{aCO_2})**. It is important for advanced emergency medical technicians (AEMTs) to understand these measurements and their implications. **pH** is the degree of acidity or alkalinity. Deviations from normal P_{aO_2} , P_{aCO_2} , and pH values occur in many different disease states.

A complicated interaction of signals provides feedback to the respiratory center, allowing it to continuously control respiration. The main respiratory stimulus is accumulation of carbon dioxide in the blood. Typically, this is measured as the P_{aCO_2} on the arterial blood gases. Increases in the P_{aCO_2} result in decreased pH levels in the respiratory center, which triggers an increase in ventilation. Decreases in the P_{aCO_2} result in increased pH levels in the respiratory center and a decrease in ventilation. Low blood oxygen levels also stimulate breathing, but normally have much less of an effect than does the P_{aCO_2} .

Essentially, P_{aCO_2} acts as respiratory acid. Changes in the P_{aCO_2} value rapidly change the pH levels, either making it more basic (increased) or

more acidic (decreased). Changes in the P_{aCO_2} can result from diseases such as asthma or COPD exacerbation, from drug overdose, or can be a response to a change in the blood pH because of a metabolic problem. A decrease in the pH of the arterial blood that is caused by an elevation in the P_{aCO_2} is called a primary **respiratory acidosis**, whereas an increase in the pH of the blood that is caused by excessive exhalation of CO_2 is called a primary **respiratory alkalosis**. Conversely, changes in the P_{aCO_2} may occur in response to primary metabolic problems (**metabolic alkalosis** or **metabolic acidosis**); these are called compensatory changes.

The body also has a backup system to control respiration called the **hypoxic drive**. When the oxygen level falls, this system will also stimulate breathing. There are areas in the brain, the walls of the aorta, and the carotid arteries that act as oxygen sensors. These sensors are easily satisfied by minimal levels of oxygen in the arterial blood. Therefore, the backup system, the hypoxic drive, is much less sensitive and less powerful than the carbon dioxide sensors in the brainstem.

Acid-Base Balance

An **acid** is a substance that increases the concentration of hydrogen ions in a water solution. A **base** is a substance that decreases the concentration of hydrogen ions.

Whether the blood or body fluid is acidic, basic, or neutral depends on the concentration of dissolved hydrogen (H^+). Hydrogen is an acid. This means that the higher the concentration, the more acidic the blood will be; conversely, the lower the H^+ concentration, the more basic (less acidic) the blood will be. Normal homeostatic functions keep the concentration of H^+ within a fairly narrow range.

The most common expression of acidity is pH, which is a value calculated from H^+ concentration:

$$pH = -\log[\text{Concentration of hydrogen ions}]$$

Therefore, the lower the hydrogen ion concentration, the greater the pH (more basic) will be, and the higher the hydrogen ion concentration, the lower the pH (more acidic) will be. pH ranges from 0 (most acidic) to 14 (most basic), with 7.0 being neutral. (The pH of pure water, which is considered neutral, is 7.0.) The pH of the human body is normally slightly basic, or alkaline, ranging approximately from 7.35 to 7.45. Normal body functions work best within this narrow range of pH. When pH is higher than this, the blood is too basic, or *alkalotic*. When pH is lower, the blood is too acidic, or *acidotic* (FIGURE 7-45). Cellular function deteriorates and death occurs when the pH drops below 6.9 or rises above 7.8.

Buffer Systems

A **buffer** is a compound that can repeatedly neutralize excess acids or bases to prevent the pH from going beyond an acceptable level. A buffer can absorb or donate H^+ . Buffers absorb hydrogen ions when they are in excess and donate hydrogen ions when they are depleted. Therefore, a **buffer system** acts as a fast defense for acid-base changes, providing

almost immediate protection against changes in the hydrogen ion concentration of the ECF. The generic reaction between a hydrogen ion and a buffer is expressed as follows:

Free H^+ (acid) binds with the buffer to form a weak acid (H-Buffer). This reaction can shift to the right or left depending on the hydrogen ion concentration. When the H^+ concentration increases and buffer is available, the reaction is forced to the right and more H-Buffer is formed. When the H^+ concentration decreases, the reaction shifts toward the left, and H^+ disassociates from the buffer, leaving H^+ and buffer.

An analogy for understanding a buffer system is to imagine it as a bucket (FIGURE 7-46). Like a bucket, the buffer system can hold only a certain amount of acid before it reaches the point at which it is saturated (the bucket is full) and overflows. The body responds to shifts in the pH level by absorbing or releasing small amounts of acid into the blood. Problems begin when the amount of acid in circulation is too great and the buffer system becomes overwhelmed.

Ion Shifts

Concentrations of H^+ ions can be increased by adding more H^+ ions to a solution or by removing OH^- . To make a **solution** more acidic, that is decrease its pH, a higher concentration of H^+ and a lower concentration of OH^- are needed. If the solution needs to be more basic, meaning increasing the pH level, there are two options:

1. Decrease the amount of H^+ .
2. Increase the amount of OH^- .

FIGURE 7-45 The pH scale.

FIGURE 7-46 Bucket analogy of the body's buffer system. **A.** Acid and base levels in the body fluctuate. **B.** The respiratory and renal systems eliminate excess acid.

© Jones & Bartlett Learning.

Acids can be classified as strong or weak, depending on how completely they dissociate (how easily they lose a hydrogen atom) in water. It is the ability of weak acids to bond weakly to hydrogen ions that makes them ideal buffers because they can accept or donate hydrogen ions, depending on the needs of the body.

To function properly, acid-base balance, or a balance of charges, must exist on both sides of the cell. If intracellular pH is low, excess H^+ ions exist in the ECF (fluid outside the cells), and H^+ ions move into the cell. This causes the cell to have an overall positive charge. To return its overall charge to neutral, the cell begins to shift cations (ions with a positive charge) into the interstitial fluid. Potassium shifts out into the ECF until no more potassium can safely be shifted out. This shift has significant consequences and can lead to hyperkalemia, a serious medical emergency.

Calcium ions also shift out of the cell in response to the influx of hydrogen. A high serum calcium level

(hypercalcemia) decreases neural transmissions (the speed at which an impulse travels through the nerve cell), whereas a low serum calcium level (hypocalcemia) leads to hypersensitive nerve cells and increased neural transmissions. An increase in extracellular H^+ ions results in **acidosis**; a decrease in extracellular H^+ ions results in **alkalosis**.

↓ pH means ↑ H^+ ion concentration = Acidosis

↑ pH means ↓ H^+ ion concentration = Alkalosis

Bone also acts as a buffer by absorbing excess acids and bases and by releasing calcium into the circulation, particularly in chronic metabolic acidosis seen with conditions like kidney disease. Types of acid-base imbalance are discussed in Chapter 8, *Pathophysiology*.

The respiratory system and the renal system work in conjunction with the bicarbonate buffer to maintain homeostasis. The fastest way the body can get rid of excess acid is through the respiratory system. Excess acid can be expelled as CO_2 from the lungs. Conversely, slowing respirations will increase CO_2 in alkalotic states. The renal system regulates pH by filtering out more hydrogen and retaining bicarbonate in acidotic states, and doing just the reverse in alkalotic states.

There are three main components to the buffer system in the body:

- The circulating bicarbonate buffer component
- The respiratory component
- The renal component

The following equation illustrates the balance among these three components:

The Circulating Bicarbonate Buffer Component

The circulating bicarbonate buffer component is the bucket that holds and neutralizes excess acid. The circulating bicarbonate buffer system is found in the ICF and ECF and is the fastest acting segment of the buffer system.

Carbonic acid (H_2CO_3) is a weak acid that can give up an extra H^+ ion to re-form as the bicarbonate ion (HCO_3^-). Through metabolic processes, the extra H^+ ion is then converted into compounds that are easily expelled from the body, eliminating the extra acid.

The Respiratory Component

The fastest way the body can get rid of the excess H^+ ions is to create water and carbon dioxide, which can be expelled as gases from the lungs. The following equation illustrates this process, which occurs in the lungs:

The main reason for breathing is to bring oxygen in for aerobic metabolism and to remove excess carbon dioxide in the blood. Carbon dioxide combines with the circulating water of the blood to create carbonic acid. Chemoreceptors in the brain sense the rising level of carbonic acid and signal the respiratory center to increase respirations and to reduce the available amount of circulating carbon dioxide. Although the respiratory component reacts within minutes, it is much slower to respond than the circulating buffer system. Consider the buffer bucket example again; the respiratory component can be thought of as a large faucet that allows acid to spill out of the buffer bucket, returning the pH to a normal level.

Anything that limits respiration can lead to acid retention and acidosis. Any time a patient is in respiratory distress or is unable to breathe, acidosis quickly develops:

A patient can develop acidosis as a result of respiratory difficulty. The following equation demonstrates this:

Alkalosis can also develop if the respiratory rate is too high (or the volume too much), as shown in the following equation:

The Renal Component

Another smaller faucet connected to the buffer bucket is the renal component. The smaller faucet

represents the slower nature by which the kidneys respond to the increasing acid level. The renal response could take from hours to days to restore the body's pH to normal. Kidneys account for every molecule, ion, and electrolyte found in the circulation; they maintain homeostasis by retaining certain products and filtering out others.

As with the respiratory system, the renal system can control the increasing acid level in the blood by excreting the acid. The kidneys excrete acid in an ionic form, unlike the respiratory system, which excretes acid as a gas.

If the patient experiences decreased urine output, excess acid cannot be removed from the blood, and acidosis can develop.

If urine output becomes excessive, alkalosis can develop.

The Nervous System Control of Breathing

The exact manner in which breathing occurs is complicated yet also poorly understood by science. It is known that the medulla oblongata—the lower half of the brainstem that, among others, controls those autonomic functions such as breathing, heart rate, and blood pressure—is primarily responsible for initiating the ventilation cycle and is primarily stimulated by high carbon dioxide levels. The function of the medulla is to keep you breathing so you do not have to think about it. The medulla has two main portions that control breathing: the **dorsal respiratory group (DRG)** and the **ventral respiratory group (VRG)**. The DRG is the main pacemaker for breathing and is responsible for initiating inspiration. It sets the base pattern for respirations. The DRG sends signals down the phrenic nerves to the diaphragm. (Originating from the cervical plexus of nerves in the neck, the phrenic nerves are among the most important nervous structures in the body.) The diaphragm contracts, and inspiration begins. The DRG shuts off, the diaphragm relaxes, and expiration begins. The VRG helps facilitate forced inspiration or expiration as needed.

The pons, another area within the brainstem, helps regulate the DRG activities. The pons has two areas. The **pneumotaxic (pontine) center**, located in the superior portion of the pons, helps shut off the DRG, resulting in shorter, faster respirations. The apneustic center, located in the inferior portion of the pons, stimulates the DRG, resulting in longer, slower respirations. Both areas of the pons are used to help augment respirations during emotional or physical stress. The two areas of the medulla and the two areas of the pons work together to help you get the right amount of air when you need it.

The VRG, pneumotaxic center, and apneustic center are involved in changing the depth of inspiration, expiration, or both. How does the body know when to stop breathing in or out? When the VRG is causing you to take a forced inspiration, what prevents you from taking in so much air that you pop your lungs like a balloon? The answer is the **Hering-Breuer reflex**. Special stretch receptors in the chest wall are able to detect if the lungs are too full or too empty. The Hering-Breuer reflex stops the VRG, pneumotaxic center, and apneustic centers from accidentally causing lung trauma. Because this reflex also increases ventilatory frequency, it maintains a constant alveolar ventilation.²

TABLE 7-6 summarizes the nervous system functions regarding respirations.

Lung Volumes

A substantial amount of air can be moved within the respiratory system. **FIGURE 7-47** shows the typical volumes. An adult male has a total lung capacity of 6,000 mL (equivalent to three 2-liter bottles of soda). An adult female has approximately one-third less total capacity because the lung size is smaller.

As you are reading this text, unless you just finished exercising, the amount of your air movement is approximately 500 mL. This is called **tidal volume**.

FIGURE 7-47 Lung volumes (mL).

TABLE 7-6 Nervous System Control of Breathing			
Name	Location	Function	Timing
Dorsal respiratory group	Medulla	Causes inspiration when stimulated	Normal, resting respirations Rhythmic, mechanical pattern
Ventral respiratory group	Medulla	Causes forced expiration or inspiration	Speech, increased emotional or physical stress
Pneumotaxic (pontine) center	Pons	Inhibits the DRG; increases speed and depth of respirations	Increased emotional or physical stress
Apneustic center	Pons	Excites the DRG; prolongs inspiration, decreases rate	Increased emotional or physical stress
Hering-Breuer inflation reflex (stretch reflex)	Chest	Detects lung expansion to a point and then tells VRG and pneumotaxic and apneustic centers to stop	Increased emotional or physical stress
Hering-Breuer deflation reflex	Chest	Detects potential lung collapse and then tells VRG and pneumotaxic and apneustic centers to stop	Increased emotional or physical stress

Abbreviations: DRG, dorsal respiratory group; VRG, ventral respiratory group

© Jones & Bartlett Learning.

Tidal volume is the amount of air that is moved into or out of the lungs during a single breath. **Inspiratory reserve volume** is the deepest breath you can take after a normal breath. Conversely, **expiratory reserve volume** is the maximum amount of air that you can forcibly breathe out after a normal breath. Gas remains in the lungs simply to keep the lungs open. This is called the **residual volume**. This gas does not move during ventilation. Some residual volume is lost when a person is hit in the chest and has the “wind knocked out of him.” **Vital capacity** is the amount of air moved in and out of the lungs with maximum inspiration and expiration.

When you assist a patient's breathing, you move air in and out of the lungs. You will use a bag-mask device—a large bag filled with air that, when squeezed, pushes air out one end. The typical bag-mask device holds approximately 1,000 to 1,200 mL of air.

Dead space is the portion of the respiratory system that has no alveoli and, therefore, little or no exchange of gas between air and blood occurs. The mouth, trachea, bronchi, and bronchioles are all considered dead space. When you ventilate a patient with any device, you create more dead space. Gas must first fill the device before it can be moved into the patient.

When you are assessing your patient, you need to accurately determine whether the patient is having trouble breathing. Often, AEMTs will look at the patient's respiratory rate; however, this rate provides only part of the information that is needed. The depth of each breath is critical information to know when assessing ventilation. Another measurement called minute volume provides you with a more accurate determination of effective ventilation. **Minute volume**, also referred to as minute ventilation, is easy to understand; it is the amount of air that moves in and out of the lungs in 1 minute.

$$\text{Minute volume} = \text{Respiratory rate} \times \text{Tidal volume}$$

This calculation helps you to determine how deeply a patient is breathing. While riding in the ambulance, it will be difficult to determine the patient's exact tidal volume, but you will be able to estimate it. Consider the scenario of a patient who is breathing at a normal rate of 20 breaths/min. Yet, when you look at the patient's chest, it is barely moving. When you feel for air movement out of the mouth, you find very little movement. The patient is in trouble and needs your assistance now! Even

though the patient's respiratory rate is normal, the amount of air being moved is inadequate. The minute volume is too low, and the patient needs ventilatory assistance. You will need to always evaluate the amount of air being moved with each breath when assessing a patient's respirations.

Characteristics of Normal Breathing

You can think of a normal breathing pattern as a bellows system. Normal breathing (eupnea) should appear easy, not labored. As with a bellows that is used to move air to start a fire, breathing should be a smooth flow of air moving into and out of the lungs.

Normal breathing has the following characteristics:

- A normal rate and depth (tidal volume)
- A regular rhythm or pattern of inhalation and exhalation
- Good audible breath sounds on both sides of the chest
- Regular rise and fall movement on both sides of the chest
- Movement of the abdomen

The Circulatory System: Anatomy

The **circulatory system** is a complex arrangement of tubes connected to one another and to a pump, including the heart and the arteries, arterioles, capillaries, venules, and veins (**FIGURE 7-48**). Another name for this system is the cardiovascular (heart/blood vessels) system. The circulatory system is entirely closed, and through arterial and venous anastomosis (connections), vessels are able to branch off to deliver blood with capillaries connecting arterioles and venules. There are two circuits in the body: the **systemic circulation** in the body and the **pulmonary circulation** in the lungs. The systemic circulation, the circuit in the body, carries oxygen-rich blood from the left ventricle through the body and back to the right atrium. In the systemic circulation, as blood passes through the tissues and organs, it gives up oxygen and nutrients and absorbs cellular wastes and carbon dioxide. The cellular wastes are eliminated in passages through the liver and kidneys. The pulmonary circulation, the circuit in the lungs, carries oxygen-poor blood from the

FIGURE 7-48 The circulatory system includes the heart, arteries, veins, and interconnecting capillaries. The capillaries are the smallest vessels and connect arterioles and venules. At the center of the system, and providing its driving force, is the heart. Blood circulates through the body under pressure generated by the two sides of the heart.

© Jones & Bartlett Learning.

right ventricle through the lungs and back to the left atrium. In the pulmonary circulation, as blood passes through the lungs, it is refreshed with oxygen and gives up carbon dioxide.

The Heart

Location and Major Structures of the Heart

The **heart** is a muscular organ that pumps blood throughout the body (**FIGURE 7-49**). The heart is located behind the sternum and is about the size of the closed fist of the person it belongs to, roughly

5 inches (13 cm) long, 3 inches (8 cm) wide, and 2 inches (5 cm) thick. It weighs 10 to 12 oz (283 to 340 g) in male adults and 8 to 10 oz (226 to 283 g) in female adults. Approximately two-thirds of the heart lies in the left part of the **mediastinum**, the area between the lungs that also contains the great vessels.

Heart muscle is called **myocardium**. The term *myo* means muscle and the word root *cardium* means heart. The **pericardium**, also called the pericardial sac, is a thick, fibrous membrane that surrounds the heart and the bases of the great vessels. The pericardium anchors the heart within the mediastinum and prevents overdistention of the heart.

Special Populations

Normal breathing patterns in infants and children are essentially the same as those in adults. However, infants and children breathe faster than adults. An infant who is breathing normally will have respirations of 30 to 60 breaths/min. A preadolescent child will have respirations of 18 to 40 breaths/min. Like adults, infants and children who are breathing normally will have smooth, regular inhalation and exhalation, equal breath sounds, and regular rise and fall movements on both sides of the chest.

Breathing problems in infants and children often appear the same as breathing problems in adults. Signs such as increased respirations, an irregular breathing pattern, unequal breath sounds, unequal chest expansion, and muscle retractions (accessory muscle use) indicate breathing problems in adults and children.

Other signs that an infant or child is not breathing normally include the following:

- Nasal flaring, in which the nostrils flare out as the child breathes
- Seesaw respirations in infants, in which the chest and abdominal muscles alternately contract to look like a seesaw

Exhalation becomes active when infants and children have trouble breathing. Normally, inhalation alone is the active, muscular part of breathing, as described earlier. However, with **labored breathing**, both inhalation and exhalation are hard work. With labored breathing, exhalation is not passive. Instead, air is forced out of the lungs during exhalation, and the child will often begin to wheeze. This type of labored breathing involves the use of the accessory muscles of breathing.

FIGURE 7-49 Anatomy of the heart.

© Jones & Bartlett Learning.

The inner membrane of the pericardium is the serous pericardium. This inner membrane contains two layers: the visceral and the parietal pericardium. The visceral layer of the pericardium lies closely against the heart and is also called the **epicardium**. The second layer of the pericardium, the parietal

pericardium, is separated from the visceral layer by a small amount of **pericardial fluid** that reduces friction within the pericardial sac. The **endocardium** is the interior lining of the heart.

The normal human heart consists of four chambers: two atria and two ventricles. The upper

chambers are the atria and the lower chambers are the ventricles. Each side of the heart contains one atrium and one ventricle. A membrane, the **interatrial septum**, separates the two atria; a thicker wall, the **interventricular septum**, separates the right and left ventricles. Each **atrium** receives blood that is returned to the heart from other parts of the body; each **ventricle** pumps blood out of the heart. The upper and lower portions of the heart are separated by the atrioventricular (AV) valves, which prevent blood from flowing backward. There are also valves located between the ventricles and the arteries into which they pump blood. These are called the **semilunar valves**.

Words of Wisdom

Complete blockage of an artery that supplies oxygen to the heart results in death to a portion of the myocardium; this event is called a **myocardial infarction**.

Blood enters the right atrium via the superior and inferior venae cavae and the **coronary sinus**, which consists of veins that collect blood that is returning from the walls of the heart. Blood from four **pulmonary veins** enters the left atrium. Between the right and left atria is a depression, the **fossa ovalis**, which represents the former location of the **foramen ovale**, an opening between the two atria that is present in the fetus.

Valves of the Heart

Blood passing from the atria to the ventricles flows through one of two **atrioventricular valves**. The **tricuspid valve** separates the right atrium from the right ventricle, and the **mitral valve**, a bicuspid valve, separates the left atrium from the left ventricle. The valves consist of flaps called cusps. **Papillary muscles** attach to the ventricles and send small muscular strands called **chordae tendineae** to the cusps. When the papillary muscle contracts, these strands tighten, preventing regurgitation of blood through the valves from the ventricles to the atria.

The two semilunar valves, the aortic valve and the pulmonic valve, divide the heart from the aorta and the pulmonary artery. The **pulmonic valve** regulates blood flow from the right ventricle to the

pulmonary artery. The **aortic valve** regulates blood flow from the left ventricle to the aorta. The semilunar valves are not attached to papillary muscles. When these valves close, they prevent backflow from the aorta and pulmonary artery into the left and right ventricles, respectively.

Blood Flow Within the Heart

Two large veins, the **superior vena cava** and the **inferior vena cava**, join together to return deoxygenated blood from the body to the right atrium. Blood from the upper part of the body returns to the heart through the superior vena cava, and blood from the lower part of the body returns through the inferior vena cava. The inferior vena cava is the larger of the two veins. From the right atrium, blood passes through the tricuspid valve into the right ventricle. Blood is then pumped by the right ventricle through the pulmonic valve into the pulmonary artery and to the lungs. In the lungs, as mentioned, various processes take place that return oxygen to the blood and, at the same time, remove carbon dioxide and other waste products.

Freshly oxygenated blood is returned to the left atrium through the pulmonary veins. Blood then flows through the mitral valve into the left ventricle, which pumps the oxygenated blood through the aortic valve, into the aorta and then to the entire body. The left ventricle is the strongest and largest of the four cardiac chambers because it is responsible for pumping blood through blood vessels throughout the body.

Heart Sounds

Heart sounds are created by the contraction and relaxation of the heart and flow of blood. These sounds can be heard during auscultation with a stethoscope. Normal heart sounds are often described as sounding like “lub-DUB, lub-DUB, lub-DUB. . . .” The “lub” is called the first heart sound or S_1 , and the “DUB” is called the second heart sound or S_2 (**FIGURE 7-50**). S_2 (“DUB”) is often louder than S_1 (“lub”). The sudden closure of the mitral and tricuspid valves at the start of ventricular contraction causes S_1 . The closure of both the aortic and pulmonic valves at the end of a ventricular contraction causes S_2 .

Two other heart sounds, S_3 and S_4 , are not usually heard in people with normal heart function

FIGURE 7-50 The normal S₁ and S₂ heart sounds.

© Jones & Bartlett Learning.

FIGURE 7-51 The abnormal S₃ and S₄ heart sounds.

© Jones & Bartlett Learning.

(**FIGURE 7-51**). The S₃ or third heart sound is a soft, low-pitched heart sound that occurs about one-third of the way through diastole (the period during which the ventricles are relaxed). When an S₃ sound is present, the heart beat cycle is described as sounding like "lub-DUB-da." This sound may correlate to a period of rapid ventricular filling. Although the S₃ sound sometimes is present in healthy young people, it most commonly is associated with abnormally increased filling pressures in the atria secondary to moderate to severe heart failure.

The S₄ heart sound is a medium-pitched sound that occurs immediately before the normal S₁ sound. When an S₄ sound is present, the heart contraction cycle sounds like "bla-lub-DUB." The S₄ sound represents either decreased stretching (compliance) of the left ventricle or increased pressure in the atria. An S₄ heart sound is almost always abnormal.

Four other sounds, all abnormal, may be heard when auscultating the heart and great vessels. Some of these sounds are very easy to hear; others may require years of experience to identify. These additional abnormal sounds include murmurs,

bruits, clicks, and snaps. A **murmur** is an abnormal "whooshing" sound heard over the heart that indicates turbulent blood flow within the heart. Although many murmurs are functional (benign) and often go away, several are characteristic of heart disease. A **bruit** is an abnormal whooshing sound heard over a main blood vessel that indicates turbulent blood flow within the blood vessel. A bruit often indicates localized atherosclerotic disease (plaque formation in the arteries). Both clicks and snaps indicate abnormal cardiac valve function. They occur at different times in the cardiac cycle, depending on which valve is diseased. Although these sounds are important, most are fleeting and difficult to hear.

The Electrical Conduction System

The mechanical pumping action of the heart occurs in response to an electrical stimulus. This impulse causes the heart to beat via a set of complex chemical changes within the myocardial cells. The brain partially controls the heart's rate and strength of contraction via the autonomic nervous system. The myocardium is the only muscle that has the

FIGURE 7-52 The cardiac conduction system. Specialized groups of cardiac muscle cells initiate an electrical impulse throughout the heart. The conduction pathway travels through the six parts of the cardiac conduction system, starting at the sinoatrial node.

© Jones & Bartlett Learning.

property of automaticity, or the ability to generate its own electrical impulses. Therefore, the contractions are initiated within the heart itself, in a group of complex electrical tissues that are part of a **conduction system**. The cardiac conduction system consists of six parts (**FIGURE 7-52**):

- The sinoatrial (SA) node
- The AV node
- The bundle of His
- The right and left bundle branches
- The Purkinje fibers

The **sinoatrial (SA) node** is located high in the right atrium and is the normal site of origin of the electrical impulse. It is the heart's natural pacemaker. Impulses originating in the SA node travel through the right and left atria, resulting in atrial contraction. The impulse then travels to the **atrioventricular (AV) node**, located in the right atrium adjacent to the septum, where it transiently slows. Electrical stimulation of the heart

muscle then continues toward the **bundle of His**, which is a continuation of the AV node. From here, it proceeds rapidly to the right and left bundle branches, stimulating the intraventricular septum. The impulse then spreads out, via the Purkinje fibers, to the left and then to the right ventricular myocardium, resulting in ventricular contraction or systole.

Regulation of Heart Function

The heart's **chronotropic state** (control of the rate of contraction), **dromotropic state** (control of the rate of electrical conduction), and **inotropic state** (control of the strength of contraction) are provided by the brain via the autonomic nervous system, the hormones of the endocrine system, and the heart tissue. Receptors in the blood vessels, kidneys, brain, and heart constantly monitor body functions to help maintain homeostasis. Baroreceptors and chemoreceptors are also involved in regulation of

heart function. **Baroreceptors** respond to changes in pressure, usually within the heart or the main arteries. **Chemoreceptors** sense changes in the chemical composition of the blood. If either of these types of receptors sense abnormalities, they transmit nerve signals to the appropriate organs. As a result, hormones or neurotransmitters are released to correct the situation. The transmission of nerve signals stops when conditions return to normal.

Stimulation of receptors often causes activation of either the parasympathetic or sympathetic branches of the autonomic nervous system, affecting both the heart rate and the strength of heart muscle contraction (**contractility**). Parasympathetic stimulation slows the heart rate, primarily by affecting the AV node. Sympathetic stimulation has two potential effects, alpha effects or beta effects, depending on which nerve receptor is stimulated. **Alpha effects** occur when alpha receptors are stimulated, resulting in vasoconstriction. **Beta effects** occur when beta receptors are stimulated, resulting in increased inotropic, dromotropic, and chronotropic states.

Epinephrine and norepinephrine, also referred to as catecholamines, are naturally occurring hormones that also may be given as cardiac drugs. Epinephrine has a greater stimulatory effect on beta receptors, and norepinephrine has predominant stimulatory actions on alpha receptors.

The Cardiac Cycle

The process that creates the pumping of the heart is known as the **cardiac cycle**. This cycle begins with myocardial contraction and concludes at the beginning of the next contraction. The heart's contraction results in pressure changes within the cardiac chambers, resulting in the movement of blood from areas of high pressure to areas of low pressure.

Systole is a term that refers to the contraction of the ventricular mass and the pumping of blood into the systemic circulation. During systole, a pressure is created within the arteries that can be recorded and is known as the systolic blood pressure. A normal systolic blood pressure in an adult is between 110 and 140 mm Hg. A pressure also exists in the vessels during **diastole**, the relaxation phase of the heart cycle, and is called the diastolic blood pressure. A normal diastolic blood pressure in an adult

is between 70 and 90 mm Hg. The **pulse pressure** is the difference between the systolic and diastolic pressures:

$$\text{Pulse pressure} = \text{Systolic pressure} - \text{Diastolic pressure}$$

Blood pressure is noted as a fraction, and the systolic reading is placed above the diastolic reading (for example, a systolic reading of 140 and a diastolic reading of 70 would be noted as 140/70 mm Hg). The unit of measure mm Hg refers to millimeters of mercury and describes the height, in millimeters, to which the blood pressure elevates a column of liquid mercury in a glass tube. Although most blood pressure measurement devices now use dials or other non-mercury-dependent sensors, blood pressure is still described in millimeters of mercury.

The pressure in the aorta against which the left ventricle must pump blood is called the **afterload**. The greater the afterload, the harder it is for the ventricle to eject blood into the aorta, reducing the **stroke volume (SV)**, or the amount of blood ejected per contraction. To a large degree, afterload is governed by arterial blood pressure. Afterload is greater with vasoconstriction and less with vasodilation.

Cardiac output is the amount of blood pumped through the circulatory system in 1 minute. Cardiac output is expressed in liters per minute (L/min). The cardiac output equals the heart rate multiplied by the stroke volume:

$$\text{Cardiac output} = \text{Stroke volume} \times \text{Heart rate}$$

Factors that influence the heart rate, the stroke volume, or both will affect cardiac output and, thus, oxygen delivery (perfusion) to tissue.

Starling Law

Increased venous return to the heart stretches the ventricles, resulting in increased cardiac contractility. This relationship has become known as the **Starling law** of the heart.

In a mechanical piston pump, the stroke volume is a fixed quantity related to the distance traveled by the piston. The heart, by contrast, has several ways of increasing stroke volume. To begin with, one of the characteristics of cardiac muscle is that when it is stretched, it contracts with greater force. That property is called the Frank-Starling mechanism, or

the Starling law, after the men who first described it. If for any reason an increased volume of blood is returned from the systemic veins to the right heart, or from the pulmonary veins to the left heart, the muscle surrounding the cardiac chambers will have to stretch to accommodate the larger volume. The more the cardiac muscle stretches, the greater will be the force of its contraction, the more completely it will empty, and therefore the greater the stroke volume will be. The amount of blood returning to the right atrium may vary somewhat from minute to minute, but the normal heart continues to pump out the same percentage of blood returned. This is called the **ejection fraction**.

Recall our equation:

$$\text{Cardiac output} = \text{Stroke volume} \times \text{Heart rate}$$

Any increase in stroke volume, with the heart rate held constant, will cause an increase in the overall cardiac output. The pressure under which a ventricle fills is called the **preload** and is influenced by the volume of blood returned by the veins to the heart.³ In situations of increased oxygen demand, the body returns more blood to the heart (preload increases), and cardiac output therefore increases as described in the Starling law. In the diseased heart, the same mechanism is used to achieve a normal resting cardiac output (that is why some diseased hearts become enlarged).

Words of Wisdom

The Starling law states that primarily the length of fibers constituting the heart's muscular wall determines the force of the heartbeat. In other words, an increase in diastolic filling increases the force of the contraction.

Think of stretching a rubber band: the further it is stretched, the greater the strength of the recoil.

The Vascular System

Blood is transported through the body in the **arteries**, which carry blood away from the heart, and **veins**, which carry blood back to the heart. Arteries become smaller as they get farther from the heart. Eventually, they branch into many small **arterioles** that divide even further into **capillaries**, which are microscopic, thin-walled blood vessels. Oxygen and

nutrients pass out of the capillaries into the cells, and carbon dioxide and waste products such as lactic acid pass from the cells into the capillaries by diffusion (**FIGURE 7-53**).

After oxygenated blood has been delivered in the capillaries, deoxygenated blood is returned to

FIGURE 7-53 Diffusion. Oxygen and nutrients pass easily from the capillaries into the cells, and waste and carbon dioxide pass from the cells into the capillaries.

© Jones & Bartlett Learning.

the heart, starting from the capillaries. The capillaries eventually enlarge to form venules, which merge together and form veins. Eventually, the veins empty into the superior and inferior vena cavae and, finally, the heart. From there it travels to the lungs, where blood is reoxygenated and the process begins again.

The walls of the blood vessels are composed of three layers of tissue (**FIGURE 7-54**). The smooth,

thin, inner lining is called the **tunica intima**, or endothelium. The middle layer, the **tunica media**, is composed of elastic tissue and smooth muscle cells that allow the vessels to expand or contract in response to changes in blood pressure and tissue demand. It is the thickest of the three tissue layers. The outer layer of tissue is called the **tunica adventitia** and consists of elastic and fibrous connective tissue.

Circulation to the Heart

The heart, like any other muscle, requires oxygen and nutrients. These are supplied via the **coronary arteries**, which arise from the aorta shortly after it leaves the left ventricle. Coronary arteries receive their blood supply during the diastolic phase. The coronary circulation emanates from the left and right coronary arteries (**FIGURE 7-55**).

The right coronary artery divides into nine important branches. Not all branches are always present in all people. These branches supply blood to the walls of the right atrium and ventricle, a portion of the inferior part of the left ventricle, and portions of the conduction system (the sinus and AV nodes). When vessels to the conduction system fail to arise from the right coronary artery, they originate from the left side instead.

The left main coronary artery is the largest and shortest of the myocardial blood vessels. It rapidly divides into two branches, the **left anterior descending (LAD) artery** and the **circumflex coronary arteries**. These arteries subdivide further, supplying blood to most of the left ventricle, the intraventricular septum, and, at times, the AV node.

Pulmonary Circulation

As discussed previously, the pulmonary circulation carries blood within the body from the right side of the heart to the lungs and back to the left side of the heart, and the systemic circulation is responsible for blood flow throughout the body. Deoxygenated blood from the right ventricle is pumped through the pulmonic valve into the pulmonary artery. This artery rapidly divides into the right and left pulmonary arteries. These arteries transport the blood to the right and left lungs. Inside the lungs, the arteries branch, becoming smaller and smaller. At the level of the capillary, waste products are exchanged and the blood is reoxygenated. The reoxygenated blood travels through venules into the pulmonary

FIGURE 7-54 The walls of the blood vessels are composed of three layers of tissue: the endothelium, elastic tissue, and connective tissue. **A.** Artery. **B.** Capillary. **C.** Vein.

YOU are the Provider

Part 3

You apply direct pressure and a dressing over the abdominal wound and the arm wound, and an occlusive dressing on the chest wound. You instruct a police officer to assist in placing the patient on a nonrebreathing mask at 15 L/min. As you and your partner place the patient on the stretcher, you examine his back and find no wounds. You then quickly move him into the back of the ambulance. You obtain the following vital signs:

Recording Time: 4 Minutes

Respirations	12 breaths/min, shallow
Pulse	Unobtainable L radial, 126 via R radial
Skin	Cool, pale, and clammy
Blood pressure	86/54 mm Hg
Oxygen saturation (SpO₂)	95% on 15 L/min
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

- What are the possible results of respiratory compromise in this patient?
- What type of shock is this patient most likely experiencing?

veins. The four pulmonary veins empty into the left atrium, two from each lung (see Figure 7-47).

Systemic Arterial Circulation

Oxygenated blood leaves the heart through the aortic valve and passes into the aorta. From the aorta, blood is distributed to all parts of the body (**FIGURE 7-56**). All arteries of the body are derived from the aorta. The aorta is divided into three portions: the ascending aorta, the aortic arch, and the descending aorta.

The **ascending aorta** arises from the left ventricle and consists of only two branches, the right and left main coronary arteries. The aorta then arches posteriorly and to the left, forming the aortic arch. Three major arteries arise from the **aortic arch**: the brachiocephalic (innominate) artery, the left common **carotid artery**, and the left subclavian artery.

The **descending aorta** is the longest portion of the aorta and is subdivided into the thoracic aorta and the abdominal aorta. The descending aorta extends through the thorax and abdomen into the pelvis. In the pelvis, the descending aorta divides into the two common iliac arteries, which further divide into the internal and external iliac arteries.

The Head and Neck

The brachiocephalic artery is the first vessel to branch from the aortic arch. It is relatively short and rapidly divides into the right common carotid artery and the right subclavian artery. The carotid arteries transport blood to the head and neck, whereas the subclavian arteries transport blood to the upper extremities.

Each common carotid artery branches at the angle of the mandible into the internal and external carotid arteries. This point of division is called the carotid bifurcation. Here, a slight dilation, the carotid sinus, contains the baroreceptors mentioned earlier—structures that are important in regulating blood pressure (these are also found in the aortic arch). Branches of the external carotid artery supply blood to the face, nose, and mouth. The internal carotid arteries, together with the vertebral arteries (branches of the subclavian arteries), supply blood to the brain (**FIGURE 7-57**).

The Upper Extremity

The **subclavian artery** supplies blood to the brain, neck, anterior chest wall, and shoulder. Shortly after its point of origin, the subclavian artery gives

rise to the vertebral arteries. The subclavian system then continues from the thorax into the upper extremity. At the shoulder joint, it becomes the axillary artery, and then the **brachial artery** below the head of the humerus. The brachial artery eventually divides into the ulnar and radial arteries at the level of the forearm (**FIGURE 7-58**).

The Thoracic Aorta

Two types of branches of arteries make up the thoracic aorta: the visceral arteries and the parietal arteries. Visceral arteries supply blood to the thoracic organs, and parietal arteries supply blood to the thoracic wall.

The right brachiocephalic and left subclavian arteries and their branches, the internal thoracic arteries (also known as the mammary arteries), the carotid arteries, and the anterior and posterior intercostal arteries, branch off the aorta and provide the blood supply to the thoracic cavity. Intercostal arteries run along the ribs and provide circulation to the chest wall. Intercostal arteries branch into anterior and posterior intercostal arteries. The anterior intercostal arteries originate as branches of the subclavian system. The posterior intercostal arteries arise directly from the aorta. Visceral branches of the thoracic aorta supply the bronchial arteries in the lungs and the esophageal arteries.

The Abdominal Aorta

Like their thoracic counterpart, branches of the abdominal aorta are divided into visceral and parietal portions. The visceral arteries are subdivided into paired and unpaired arteries. The three major unpaired branches of the abdominal aorta's visceral arteries include the celiac trunk, the superior mesenteric, and the inferior mesenteric arteries (**FIGURE 7-59**). The celiac trunk supplies blood to the esophagus, stomach, duodenum, spleen, liver, and pancreas (**FIGURE 7-60**). The superior mesenteric artery and its branches supply blood to the pancreas, small intestine, and colon. The inferior mesenteric artery and its branches supply blood to the descending colon and rectum. Paired branches of the visceral abdominal aorta supply blood to the kidneys, adrenal gland, and gonads. The parietal branches supply blood to the diaphragm and abdominal wall.

The Pelvis and Lower Extremity

At the level of the fifth lumbar vertebra, the aorta divides into the two common iliac arteries. These

FIGURE 7-56 The principal arteries supply blood to a vast network of smaller arteries and arterioles. Venules deliver oxygen-poor blood to the veins that return blood to the heart.

© Jones & Bartlett Learning.

arteries further divide into the internal iliac arteries, which supply blood to the pelvis, and the external iliac arteries, which enter the lower extremity (**FIGURE 7-61**). The internal iliac artery sends out visceral branches to the rectum, vagina, uterus, and ovary. Parietal branches supply blood to the sacrum, gluteal muscles of the buttocks region, the pubic region, rectum, external genitalia, and proximal thigh.

Similar to the upper extremity, the vessels of the lower extremity form a continuum. The external

**FIGURE 7-61** The arteries of the pelvis and thigh.

© Jones & Bartlett Learning.

iliac arteries become the **femoral arteries**. Each femoral artery supplies blood to the thigh, external genitalia, anterior abdominal wall, and knee. The femoral artery becomes the **popliteal artery** in the lower thigh. Each popliteal artery then branches into the anterior tibial, posterior tibial, and peroneal arteries. At the foot, the anterior tibial artery becomes the **dorsalis pedis artery**. Plantar arteries arise from the **posterior tibial artery** and subdivide into digital branches that supply blood to the toes (**FIGURE 7-62**).

The Systemic Venous Circulation

As a rule, veins accompany the major arteries. Many veins generally have the same names as the arteries they accompany.

The Head and Neck

The two major veins that drain the head and neck are called the external and internal **jugular veins**. The external jugular vein is more superficial and often is visible immediately beneath the skin. The external

**FIGURE 7-62** The arteries of the lower extremity.

© Jones & Bartlett Learning.

jugular vein primarily drains the posterior head and neck. The internal jugular vein drains the cranial vault as well as the anterior portion of the head, face, and neck. Spaces between membranes surrounding the brain form **venous sinuses**. These sinuses are the primary means of venous drainage from the brain and feed into the internal jugular vein.

The external and internal jugular veins join the **subclavian veins** (the proximal part of the main vein of the arm) (**FIGURE 7-63**) to form the brachiocephalic veins, which drain into the superior vena cava.

The Upper Extremity

The veins of the upper extremity vary somewhat from person to person (**FIGURE 7-64**). The names of the veins of the hands, wrists, and forearm follow the arteries of the same name. In the upper forearm, these veins combine to form the **basilic vein** and the cephalic vein, the major veins of the arm. The basilic and cephalic veins combine to form the **axillary vein**, which drains into the subclavian vein.

FIGURE 7-63 The veins of the head and neck.

© Jones & Bartlett Learning.

FIGURE 7-64 The veins of the upper extremity.

© Jones & Bartlett Learning.

The Thorax

In the thorax, venous drainage begins at the anterior and posterior intercostal veins. The intercostal veins empty into the azygos vein on the right side of the thorax and the hemiazygos vein on the left side. These veins, along with the right and left

FIGURE 7-65 The hepatic portal system.

© Jones & Bartlett Learning.

brachiocephalic veins, provide the major source of flow into the superior vena cava.

The Abdomen and Pelvis

Ultimately, all venous drainage from the lower part of the body passes through the inferior vena cava. The inferior vena cava returns deoxygenated blood from the lower parts of the body to the right atrium for oxygenation. Within the abdominal and pelvic cavities, veins of the same name accompany the major arteries, providing venous drainage from structures including the kidney, adrenal glands, gonads, and diaphragm. The internal iliac veins drain the pelvis, and the external iliac veins drain the lower limbs. The internal and external iliac veins combine together in the pelvis, forming the common iliac veins, which combine to form the inferior vena cava.

The **hepatic portal system** is a specialized part of the venous system that drains blood from the liver, stomach, intestines, and spleen (**FIGURE 7-65**). Blood from the system flows first through the liver, where blood collects in sinusoids. In the sinusoids, the liver extracts nutrients, filters the blood, and metabolizes various drugs. The blood then empties into the **hepatic veins**, which join the inferior vena cava.

The Lower Extremity

The longest vein in the body is the great **saphenous vein**. It drains the foot, leg, and thigh. The saphenous vein originates over the dorsal and medial side of the foot, ascends along the medial side of the leg and thigh, and empties into the **femoral vein**, which then drains into the external iliac vein. Laterally, the

FIGURE 7-66 The veins of the lower extremity.

© Jones & Bartlett Learning.

small saphenous vein helps drain the leg and lateral side of the foot. The veins of the feet also drain into the anterior and posterior tibial veins, which accompany their respective arteries, uniting at the knee to form the popliteal vein. The popliteal vein ascends through the thigh, becoming the femoral vein (**FIGURE 7-66**).

Blood Composition

Blood is the substance that is pumped by the heart through the arteries, veins, and capillaries. Blood consists of plasma (55%) and formed elements or cells that are suspended in the plasma (45%). These cells include RBCs, WBCs, and platelets. The purpose of blood is to transport oxygen and nutrients to the tissues and carry cell waste products away from the tissues. In addition, the formed elements are the mainstay of numerous other body functions such as fighting infection and controlling bleeding. Human adult male bodies contain approximately 70 mL/kg (approximately 5 L) of blood, whereas female bodies contain approximately 65 mL/kg.

Plasma is a watery, straw-colored fluid that accounts for more than one-half of the total blood volume. Plasma is made up of 92% water and 8% dissolved substances such as proteins, electrolytes, and nutrients. All other components together make up 1% of the plasma:

- **Water.** Constitutes 92% of plasma
- **Proteins.** Constitute 7% of the plasma. Most of this protein is albumin, which functions mainly to regulate oncotic pressure, and thereby controls the movement of water into and out of the circulation. Also includes clotting factors, enzymes, and some hormones
- **Oxygen.** Little oxygen is dissolved in the plasma; almost all oxygen is bound to hemoglobin.
- **Carbon dioxide.** Transported as bicarbonate in the plasma
- **Nitrogen.** The air that we breathe is mostly nitrogen; therefore, this gas is dissolved within the plasma.
- **Nutrients.** Fuel for the cells
- **Cellular wastes.** Lactic acid, carbon dioxide, etc
- **Others.** Hormones, other cellular products

Water enters the plasma from the digestive tract, from fluids between cells, and as a by-product of metabolism.

In adults, blood cells are most commonly manufactured in the red bone marrow of the sternum, ribs, vertebral bodies, pelvis, and proximal portions of the femur and humerus. Each day, the body produces billions of new RBCs, WBCs, and platelets from the stem cells that are present in the bone marrow, thereby replacing those that have been lost or are no longer functional.

Red Blood Cells

Red blood cells (RBCs) carry oxygen to the tissues. They are disk-shaped and are also known as erythrocytes. These are the most numerous of the formed elements in the blood. A typical human has between 4.2 and 5.8 million erythrocytes per cubic millimeter of blood. RBCs are unable to move on their own; the flowing plasma passively propels them. RBCs contain a protein known as hemoglobin, which gives them their red color. Hemoglobin carries oxygen from the lungs and to the tissues by binding to it.

Erythropoiesis is the ongoing process by which RBCs are made. In hypoxic states (such as anemia), RBC production is increased.⁴ Approximately 25 trillion RBCs are contained in the normal adult

circulation; of these, 2.5 million erythrocytes are destroyed every second.

RBCs have a finite life span of 120 days. Those cells destined for destruction decompose in the spleen and other tissues rich in cells known as **macrophages**. Macrophages protect the body against infection. The body recycles some components of hemoglobin, such as the protein, globin, and iron. The part of hemoglobin that is not recycled is converted to **bilirubin**, which is a waste product that undergoes further metabolism in the liver. Normally, a chemical derivative of bilirubin, urobilinogen, is excreted in the stool and in the urine.

ABO and Rh Blood Groups

RBCs contain antigens on their surface. An **antigen** is a substance that, when taken into the body, stimulates the formation of a specific protective protein called an **antibody**. After antibodies are formed and exist within the plasma, they react with antigens. To ensure compatibility and prevent medical complications during blood component replacement, people are classified as having one of four blood types based on the presence or absence of these specific antigens. This process of classification is referred to as blood typing, or determining the ABO blood group. In the ABO system, the RBC classification types are O, A, B, and AB (TABLE 7-7).

Type A blood contains RBCs with type A surface antigens and plasma containing type B antibodies; type B blood contains type B surface antigens and plasma containing type A antibodies. Type AB blood contains both types of antigens but the plasma contains no ABO antibodies. Type O contains neither A nor B antigens but contains both A and B plasma antibodies. A person's blood type

determines which type of blood the person may receive in a blood transfusion. A person with type O blood is called a *universal donor*, because type O blood can be given to anyone, no matter their blood type, without an adverse reaction occurring. Also, a person with type AB blood can accept any type of blood—A, B, AB, or O—without an adverse reaction occurring; therefore, a person with type AB blood is called a *universal recipient*.

Another antigen, called Rh antigen, can exist in the blood as well. A person can have **Rh factor**, a specific type of Rh antigen, present in their blood or not; they can be Rh-positive if the antigen exists or Rh-negative if it does not. This can be very problematic in pregnancy. The fetus inherits the father's Rh factor, so when a woman who is Rh-negative is pregnant with a child who is Rh-positive, the woman's body will produce antibodies if exposed to the Rh factor. Those antibodies can attack future pregnancies, if the fetus is Rh-positive. Treatment can be initiated to prevent this situation.

The presence of Rh factor must also be considered during blood administration. If individuals develop antibodies to Rh antigen (after first being exposed to it), then they can have a severe hemolytic reaction the next time they are exposed to it.

Words of Wisdom

A decrease in the number of RBCs in the body, creating a deficiency of hemoglobin, is called anemia. Causes of anemia include inadequate nutrition (such as iron deficiency), inadequate production of RBCs by bone marrow, increased destruction of RBCs by the body (hemolysis), or bleeding.

TABLE 7-7 ABO Blood Groups			
Blood Type	Antigen	Antibody	Potential Donor
A	A	Anti-B	A, O
B	B	Anti-A	B, O
AB	A and B	Neither antibody	AB, A, B, O
O	Neither antigen	Anti-A and Anti-B	O

White Blood Cells

White blood cells (WBCs) are also known as leukocytes. There are several different types of WBCs and each has a different function. The primary function of all WBCs is to fight infection. Antibodies to fight infection may be produced, or WBCs may directly attack and kill bacterial invaders. WBCs are larger than RBCs. Most WBCs are motile and leave the blood vessels by a process known as **diapedesis** to move toward the tissue where they are needed most.

WBCs are named according to their appearance in a stained preparation of blood. In general, **granulocytes** have large cytoplasmic granules that

are easily seen with a simple light microscope; **agranulocytes** are WBCs that lack these granules. There are three types of granulocytes (neutrophils, eosinophils, and basophils) and two types of agranulocytes (monocytes and lymphocytes).

Neutrophils are normally the most common type of granulocyte in the blood. Neutrophils destroy bacteria, antigen-antibody complexes, and foreign matter. **Eosinophils** are granulocytes that contain granules that stain bright red with the acidic stain eosin. Eosinophils function in the body's allergic response and are, thus, increased in people with allergies. Certain parasitic infections, such as trichinosis, also result in an increase in the number of eosinophils present. **Basophils** are the least common of all granulocytes and play a role in both allergic and inflammatory reactions. Basophils contain large amounts of **histamine**, a substance that increases tissue inflammation, and **heparin**, a substance that inhibits blood clotting.

Lymphocytes are the smallest of the agranulocytes. Lymphocytes originate in the bone marrow but migrate through the blood to the lymphatic tissues. Most lymphocytes are located in the lymph nodes, spleen, tonsils, lymph nodules, and thymus.

Monocytes and macrophages are among the first lines of defense in the inflammatory process. Monocytes migrate out of the blood and into the tissues in response to an infection. They engulf microbes and digest them in a process called phagocytosis. Unlike their counterparts, the neutrophils, which are short-lived, monocytes mature into long-lived macrophages when in the tissues.

Platelets and Blood Clotting

Platelets are small cells in the blood that are necessary for the series of chemical reactions that occur to form a clot. The blood clotting or coagulation process is a complex set of events involving platelets, clotting proteins in the plasma (clotting factors), other proteins, and calcium. The process begins with platelets clumping together. Clotting proteins produced by the liver then solidify the remainder of the clot, which eventually includes RBCs and WBCs.

Following injury to a blood vessel wall, a predictable series of events takes place, resulting in **hemostasis** (cessation of bleeding) and formation of the final blood clot. Chemicals released from the vessel wall cause local vasoconstriction, as well as

activation of the platelets. The combination of vessel contraction and loose platelet aggregation forms a temporary plug. Other factors released by the tissues, known as tissue thromboplastin, activate a cascade of clotting proteins. Eventually, **thrombin** is formed. This causes the conversion of fibrinogen to **fibrin**, which binds to the platelet plug, forming the final mature clot.

The body also has two systems to counterbalance the clotting system. One, the fibrinolytic system, lyses or disrupts clots that already have formed. The main steps in the fibrinolytic system are the activation of **tissue plasminogen activator (t-PA)**, which converts plasminogen to **plasmin**.

Together, the fibrinolytic system and the body's own anticoagulants attempt to provide a balance between clotting and bleeding; however, neither system is completely effective (for example, in patients where clot formation is creating problems, such as myocardial infarction or stroke, as well as in patients with spontaneous bleeding, such as subarachnoid hemorrhage or hemophilia).

The Circulatory System: Physiology

The **pulse**, which is palpated most easily at the neck, wrist, or groin, is created by the forceful pumping of blood out of the left ventricle and into the major arteries. It is present throughout the entire arterial system. It can be felt most easily where the larger arteries are near the skin. The central pulses are the carotid artery pulse, which can be felt at the upper portion of the neck, and the femoral artery pulse, which is felt in the groin. The peripheral pulses include the radial pulse, which is felt at the wrist at the base of the thumb; the brachial artery pulse, which is felt on the medial aspect of the arm, midway between the elbow and shoulder; the posterior tibial artery pulse, which is felt posterior to the medial malleolus; and the dorsalis pedis artery pulse, which is felt on the top of the foot (**FIGURE 7-67**).

Blood pressure is the pressure that the blood exerts against the walls of the arteries as it passes through them. As mentioned earlier, systole and diastole are the phases that occur when the left ventricle contracts and when the ventricle relaxes, respectively. The pulsed forceful ejection of blood from the left ventricle of the heart into

FIGURE 7-67 The central and peripheral pulses can be felt where the large arteries are near the skin.

© Jones & Bartlett Learning.

the aorta is transmitted through the arteries as a pulsatile pressure wave. This pressure wave keeps the blood moving through the body. The high and low points of the wave can be measured with a **sphygmomanometer** (blood pressure cuff) and are expressed numerically in millimeters of mercury (mm Hg).

The state of the blood vessels, how dilated or constricted they are, is referred to as the **systemic vascular resistance (SVR)**. SVR is the resistance to blood flow within all blood vessels except the pulmonary vessels. The relationship between the size of the vessels and shock is important to understand. In some types of shock, blood vessels dilate and the patient's blood pressure falls dramatically (**TABLE 7-8**).

The typical adult has approximately 5 L of blood in the vascular system. Children have less (2 to 3 L) depending on their age and size. Infants have only approximately 300 mL. The loss of an amount of blood that may be negligible for an adult could be fatal for an infant.

TABLE 7-8 Effects of Blood Vessel Diameter on Blood

State	Effects
Constricted blood vessel	Decreased size of container Increased pressure within container
Normal diameter	Balance of size and pressure
Dilated blood vessel	Increased size of container Decreased pressure within container

Normal Circulation in Adults

In all healthy people, the circulatory system is automatically adjusted and readjusted constantly so 100% of the capacity of the arteries, veins, and capillaries holds 100% of the blood at that moment. All vessels are never fully dilated or constricted. The size of arteries and veins is controlled by the nervous system, according to the amount of blood that is available and many other factors, to keep blood pressure normal constantly. Under the condition of normal pressure, with a system that can hold just 100% of the blood available, all parts of the system will have adequate blood supply all the time.

Perfusion is the circulation of blood in an organ or tissue in adequate amounts to meet the tissue's current needs. Blood enters an organ or tissue through the arteries and leaves it through the veins (**FIGURE 7-68**). Loss of normal blood pressure is an indication that blood is no longer circulating efficiently to every organ in the body. (However, a "good blood pressure" does not indicate that it is reaching all parts of the body.) There are many reasons for loss of blood pressure. The result in each case is the same: organs, tissues, and cells are no longer adequately perfused or supplied with oxygen and food, and wastes can accumulate. Under these conditions, cells, tissues, and whole organs may die. The state of inadequate circulation, when it involves the entire body, is called **shock**, or hypoperfusion.

Inadequate Circulation in Adults

When a patient loses a small amount of blood, the arteries, veins, and heart automatically adjust to

FIGURE 7-68 Blood enters an organ or tissue through the arteries and leaves through the veins. This process, called perfusion, results in the blood flow to the tissue that is necessary to meet the cells' needs.

© Jones & Bartlett Learning.

the smaller new volume. The adjustment occurs to maintain adequate pressure throughout the circulatory system and maintain circulation for every organ. The adjustment occurs rapidly after the loss, usually within minutes. Specifically, the vessels constrict to provide a smaller bed for the reduced volume of blood to fill. The heart then pumps more rapidly to circulate the remaining blood more efficiently. As the blood pressure decreases, the pulse increases in an attempt to keep the cardiac output constant at 5 to 6 L/min. If the loss of blood is too great, the adjustment fails, and the patient goes into shock.

Words of Wisdom

If a patient is bleeding or severely dehydrated, baroreceptors sense the abnormally low volume of blood in the circulatory system. Although several different body responses occur at once, a major response is the release of epinephrine and norepinephrine from the adrenal glands, causing sympathetic (adrenergic) stimulation, resulting in an increased heart rate, as well as increased myocardial contractility and vasoconstriction.

The Function of Blood

The concept of blood distribution involves reservoirs. Most blood is unevenly distributed throughout the body. Approximately 30% of blood is found within the heart, arteries, and capillaries. Seventy percent of blood is found within the veins and venules. This may seem confusing, but if you remember that the heart and arteries are high-pressure systems and veins are low-pressure systems, it becomes clearer. As blood pressure falls, blood flow slows down and there is more blood in the veins.

Consider the movement of blood and its ultimate function of perfusion. Recall that capillaries are the smallest portions of the circulatory system where materials exit and enter the bloodstream. Nutrients move from the capillaries into the interstitial space and into the cells. (The **interstitial space** is the space between the cells.) Wastes move from the cells through the interstitial space and into the capillaries.

Here is a simplified version of what is happening inside the capillary: the two main forces at work inside the capillary are **hydrostatic pressure** and **oncotic pressure**. Hydrostatic pressure is pressure exerted by a liquid and occurs when blood is moved through the artery at relatively high pressures. When that blood meets the capillary walls, the pressure of the fluid pushes against the walls to force fluid out of the capillary. The opposing force is oncotic pressure. Oncotic pressure is a form of osmotic pressure exerted by proteins in the blood plasma that usually tends to pull water into the circulatory system. These proteins tend to make the blood thicker. This thickness means that relative to the interstitial space, there is more water outside the capillary than inside. Diffusion occurs, and water seeks to move into the capillary.

Here is the entire process (**FIGURE 7-69**). Blood flows into the arterial side of the capillary. Plasma is trying to enter the capillary from the interstitial space, but hydrostatic pressure on the arterial side of the capillary is higher, so plasma, carrying nutrients, leaves the capillary and enters the interstitial space. The hydrostatic pressure is greatly diminished by the time the fluid reaches the venous side of the capillary because the effort of pushing the fluid out of the capillary decreased its force. This decrease in pressure is beneficial because now oncotic pressure can push fluid into the capillary; plasma,

FIGURE 7-69 Fluid movement from capillaries to interstitial space and back.

© Jones & Bartlett Learning.

with all wastes from the cells, enters the venous side of the capillary. These wastes are then carried away.

As mentioned, another function of blood is the ability to clot. Coagulation, or clotting, occurs as the result of a complex chemical process that creates small fibers near the injured blood vessel, trapping RBCs. This chemical process involves platelets and clotting factors that are in the bloodstream. **TABLE 7-9** outlines the major functions of the blood.

The Lymphatic System

The **lymphatic system** transports lymph by passive circulation. **Lymph** is a thin, plasmalike fluid formed from interstitial fluid or ECF that bathes the tissues of the body. Lymphatic capillaries pick up the lymph and drain it into larger vessels. Lymph circulates through the body in thin-walled **lymph vessels** that travel close to the major arteries and veins (**FIGURE 7-70**). Similar to veins, lymphatic vessels contain valves that limit backflow. Foreign material such as debris or bacteria is filtered from the lymph in the **lymph nodes**, round or bean-shaped structures that are interspersed along the course of the lymph vessels, and the lymph returns to the main circulatory system via the **thoracic duct**, one of two great lymph vessels, which empties into the junction of the left subclavian vein and the left internal

TABLE 7-9 Functions of the Blood and the Components of Blood in Use

Function	Component of the Blood in Use
Fighting infection	White blood cells
Transporting oxygen	Red blood cells (hemoglobin)
Transporting carbon dioxide	Plasma
Controlling (buffering) pH	Chemicals within the plasma
Transporting wastes and nutrients	Plasma (water)
Clotting (coagulation)	Platelets and clotting factors in the plasma

© Jones & Bartlett Learning.

jugular vein. The lymphatic system helps absorb fat from the digestive tract, maintain fluid balance in the body, and fight infection.

Lymphatic Vessels

Lymphatic vessels only carry fluid away from the tissues. In the lymphatic capillaries, the epithelial

FIGURE 7-70 The lymphatic vessel. The enlarged diagram of a lymph node and vessels shows the path of the excess fluid that leaves the capillary, enters the adjacent tissue spaces, and is absorbed by lymphatic capillaries.

© Jones & Bartlett Learning.

cells contain one-way valves that allow fluid to enter the vessel but prevent it from flowing back into the tissues. Lymphatic capillaries are present in all tissues except the central nervous system, bone marrow, cartilage, epidermis, and **cornea**. Generally, fluid flows from the blood capillaries to the tissues, then out of the tissue spaces into lymph capillaries. In the major blood capillary beds of the body, the internal hydrostatic pressure allows a normal, continuous leak of a total of 3 to 4 mL/min of fluid into the interstitial spaces. To prevent the tissues from

becoming edematous, the lymphatic vessel must absorb this excess fluid and return it to the central venous circulation.

The Nervous System: Anatomy and Physiology

The **nervous system** is perhaps the most complex organ system within the human body. It is composed of two major structures, the brain and the spinal cord, and thousands of nerves that allow every part of the body to communicate. This system is responsible for fundamental functions such as controlling breathing, heart rate, and blood pressure. However, what makes the nervous system so special is that it allows the performance of higher-level activity, such as memory, understanding, and thought.

The nervous system is divided into two main portions: the **central nervous system (CNS)** and the peripheral nervous system. The **somatic nervous system** is the part of the peripheral nervous system that regulates activities over which there is voluntary control, such as walking, talking, and writing. The **autonomic nervous system** controls the many body functions that occur without voluntary control. These activities include body functions such as digestion, dilation and constriction of blood vessels, sweating, and all other involuntary actions that are necessary for basic body functions. Thus, the nervous system as a whole can be divided anatomically into the central and peripheral nervous systems and functionally into somatic (voluntary) and autonomic (involuntary) components (**FIGURE 7-71**).

The Central Nervous System

Brain

The **brain** is the controlling organ of the body. It is the center of consciousness. It is responsible for all of your voluntary body activities, your perception of your surroundings, and the control of your reactions to the environment. In addition, the brain enables you to experience all the fine shadings of thought and feeling that make each of us an individual. The brain is subdivided into several areas, all of which have specific functions. Three major subdivisions of the brain are the cerebrum, the cerebellum, and the brainstem (**FIGURE 7-72**).

The **cerebrum**, which is the largest part of the brain and is sometimes called the gray matter,

FIGURE 7-71 The basic configuration of the nervous system.

Abbreviation: CNS, central nervous system.

© Jones & Bartlett Learning.

FIGURE 7-72 The brain lies well protected within the skull. Its principal subdivisions are the cerebrum, the cerebellum, and the brainstem.

© Jones & Bartlett Learning.

makes up approximately three-fourths of the volume of the brain and is composed of four lobes: frontal, parietal, temporal, and occipital. The cerebrum on one side of the brain controls activities

on the opposite side of the body. Each lobe of the cerebrum is responsible for a specific function. For example, one group of brain cells in the frontal lobe is responsible for the activity of all the voluntary muscles of the body. Brain cells in this area generate impulses that are sent along nerve fibers that extend from each cell into the spinal cord. An area in the parietal lobe has cells that receive sensory impulses from the peripheral nerves of the body. Other parts of the cerebrum are responsible for other body functions. For example, the occipital region, in the back of the cerebrum, receives visual impulses from the eyes; other areas control hearing, balance, and speech. Still other parts of the cerebrum are responsible for emotions and other characteristics of a person's personality (**FIGURE 7-73**).

The **cerebellum**, which is located underneath the great mass of cerebral tissue, is sometimes called the athlete's brain. The major function of this area is to coordinate the various activities of the body, particularly body movements. Without the

cerebellum, specialized muscular activities such as writing would be impossible.

The **brainstem** is named such because the brain appears to be sitting on this portion of the CNS as

FIGURE 7-73 The cerebral cortex.

© Jones & Bartlett Learning.

a plant sits on its stem. The brainstem is the most primitive part of the CNS. It lies deep within the cranium and is the best-protected part of the CNS. The brainstem is the controlling center for virtually all body functions that are necessary for life. Cells in this part of the brain control cardiac, respiratory, and other basic body functions. The brainstem comprises three areas: the **midbrain**, the **pons**, and the **medulla oblongata**. One of the interesting operations of the brainstem is the regulation of consciousness. The **reticular activating system** in the midbrain keeps you conscious.

The brain has many other anatomic areas, all of which have specific and important functions. The brain receives a vast amount of information from the environment, sorts it all out, and directs the body to respond appropriately. Many of the responses involve voluntary muscle action; others are automatic and involuntary. **TABLE 7-10** summarizes

TABLE 7-10 Structures of the Nervous System and General Functions			
System	Major Structure	Subdivision	General Function
Central nervous system	Brain	Occipital lobe	Vision and storage of visual memories
		Parietal lobe	Sense of touch and texture; storage of those memories
		Temporal lobe	Hearing, smell, and language; storage of sound and odor memories
		Frontal lobe	Voluntary muscle control and storage of those memories
		Prefrontal area	Judgment and predicting consequences of actions, abstract intellectual functions
		Limbic system	Basic emotions, basic reflexes (chewing, swallowing, etc)
	Brainstem	Diencephalon (thalamus)	Relay center; filters important signals from routine signals
		Diencephalon (hypothalamus)	Emotions, temperature control, interface with endocrine system (hormone control)
		Midbrain	Level of consciousness, reticular activating system, muscle tone, and posture
		Pons	Respiratory patterning and depth
Peripheral nervous system	Spinal cord	Medulla oblongata	Heart rate, blood pressure, respiratory rate
			Reflexes, relays information to and from body
Peripheral nervous system	Cranial nerves		Brain to body part; special peripheral nerves that connect directly to body parts
	Peripheral nerves		Brain to spinal cord to body part; receive stimulus from body, send commands to body

the major portions of the nervous system and their functions.

Spinal Cord

The **spinal cord** is an extension of the brainstem (**FIGURE 7-74**). As with the brain, the spinal cord contains nerve cell bodies, but the major portion of the spinal cord is made up of nerve fibers that extend from the cells of the brain. These nerve fibers transmit information to and from the brain. All fibers join together just below the brainstem to form the spinal cord. The spinal cord exits through a large opening at the base of the skull called the foramen magnum. It is encased within the spinal canal down to the level of the second lumbar vertebra. The spinal canal is created by an opening through the vertebrae, stacked one on another. Each vertebra surrounds the cord, and together the vertebrae form the bony spinal canal.

The principal function of the spinal cord is to transmit messages between the brain and the body. These messages are passed along the nerve fibers as electrical impulses, just as messages are passed

along a telephone cable. The nerve fibers are arranged in specific bundles within the spinal cord to carry the messages from one specific area of the body to the brain and back.

Safety

CSF is a clear body fluid that can carry the same infectious diseases as blood. The risk of exposure to infectious agents from CSF can be even greater than from blood because its presence is not as obvious as blood at first sight. To avoid exposure to infectious agents, ALWAYS wear gloves when making patient contact.

The Meninges

The entire CNS is enclosed by a set of three tough membranes known as the **meninges**. The outer membrane is the **dura mater** and is the toughest membrane. The second layer is called the **arachnoid** because the blood vessels it contains have the appearance of a spider web. The innermost layer, resting directly on the brain or spinal cord, is the **pia mater**.

When a hematoma develops, it can be classified according to its location in respect to the meninges (an epidural or a subdural hematoma). The meninges float in **cerebrospinal fluid (CSF)**, which is manufactured by cells within the **choroid plexus**

FIGURE 7-74 The spinal cord is a continuation of the brainstem. It exits the skull at the foramen magnum and extends down to the level of the second lumbar vertebra in most adults.

© Jones & Bartlett Learning.

Words of Wisdom

Bleeding can occur between the meninges and the brain, usually as a result of trauma. The most common type of bleeding occurs with a **subarachnoid hemorrhage**, in which the blood lies between the arachnoid and the pia mater.

Words of Wisdom

In patients with a fracture at the base of the skull, CSF can leak into the eustachian tubes, past the eardrums, and out through the ears. Because CSF does not mix well with blood, it sometimes appears as a halo of clear fluid around drops of blood when it leaks onto a gauze pad. CSF that leaks into the back of a patient's throat is often described as having a "salty" taste.

in the ventricles, hollow storage areas in the brain. These areas normally are interconnected, and CSF flows freely within the **subarachnoid space**. The subarachnoid space is located between the pia mater and the arachnoid membrane. CSF is similar in composition to plasma. The meninges and CSF form a fluid-filled sac that cushions and protects the brain and spinal cord.

The Diencephalon

The **diencephalon**, which is located between the brainstem and the cerebrum, includes the thalamus, subthalamus, hypothalamus, and epithalamus. The **thalamus** processes most sensory input and influences mood and general body movements, especially those associated with fear and rage. The subthalamus controls motor functions. The functions of the epithalamus include regulation of circadian rhythms, mood, and motor pathways. The most inferior portion of the diencephalon, the **hypothalamus**, is vital in the control of many body functions, including heart rate, digestion, sexual development, temperature regulation, emotion, hunger, thirst, vomiting, and regulation of the sleep cycle. Portions of the cerebrum and diencephalon constitute the limbic system.

The Limbic System

The **limbic system** is the so-called emotional brain, or the feeling and reacting brain. It influences emotions, motivation, mood, and sensations of pain and pleasure (**FIGURE 7-75**). The limbic system also has roles in learning and short- and long-term memory.

The Peripheral Nervous System

Many of the cells in the CNS have long fibers that extend from the cell body out through openings in the bony covering of the spinal canal to form a cable of nerve fibers that link the CNS to the various organs of the body. These cables of nerve fibers make up the **peripheral nervous system (PNS)**. The PNS is divided into two portions. The first is the somatic nervous system that transmits signals from the brain to the voluntary muscles. As you turn the page of this text, you are accessing your somatic nervous system.

The other portion of the PNS is the autonomic nervous system, which, in turn, is split into two

FIGURE 7-75 The limbic system.

© Jones & Bartlett Learning.

areas. The **sympathetic nervous system** is responsible for the fight-or-flight response, enabling you to fight if you find yourself in a dangerous situation or to run away. This fight-or-flight response generally increases the activity within your body so that your muscles are able to perform more effectively. Sympathetic responses include the shunting of blood from the extremities to the vital core organs, increasing the heart rate and respirations, increasing blood pressure, dilation of the pupils, and reduction of digestive system activity.

The **parasympathetic nervous system**, the other half of the autonomic nervous system, generally slows down the body—hence, the mnemonic “rest and digest.” When you are eating, your blood supply needs to move to your stomach and intestines so the food you eat can be processed. The parasympathetic responses include slowing the heart and respiratory rates, lowering the blood pressure, constricting the pupils, and increasing digestive system activity.

There are two types of nerves within the peripheral nervous system. **Sensory nerves** carry information from the body to the CNS. **Motor nerves** carry information from the CNS to the muscles of the body.

Sensory Nerves

Sensory nerves of the body are quite complex. There are many types of sensory cells in the nervous system. One type forms the retina of the eye; others are

responsible for the hearing and balancing mechanisms in the ear. Other sensory cells are located in the skin, muscles, joints, lungs, and other organs of the body. When a sensory cell is stimulated, it transmits its own special message to the brain. There are special sensory nerves to detect heat, cold, position, motion, pressure, pain, balance, light, taste, and smell, as well as other sensations. Specialized nerve endings are adapted for each cell so it perceives only one type of sensation and transmits only that message.

The sensory impulses constantly provide information to the brain about what the different parts of our body are doing in relation to our surroundings. Thus, the brain is continuously made aware of its surroundings. The cranial nerves supply sensations directly to the brain. Visual sensations (what we see) reach the brain directly by way of the optic nerve (the second cranial nerve) in each eye. The nerve endings for the optic nerve lie in the retina of the eye. The nerve endings are stimulated by light, and the impulses travel along the nerve that passes through a hole in the back of the eye socket and carries impulses to the occipital portion of the brain.

When sensory nerve endings in the extremities are stimulated, the impulses are transmitted along a peripheral nerve to the spinal cord. The cell body of the peripheral nerve lies in the spinal cord. The impulse is then transmitted from that cell body to another nerve ending in the spinal cord and from there up the spinal cord to the sensory area in the parietal lobe of the brain, where the sensory information can be interpreted and acted on by the brain.

Motor Nerves

Each muscle in the body has its own motor nerve. The cell body for each motor nerve lies in the spinal cord, and a fiber from the cell body extends as part of the peripheral nerve to its specific muscle. Electrical impulses that are produced by the cell body in the spinal cord are transmitted along the motor nerve to the muscle and cause it to contract. The cell body in the spinal cord is stimulated by an impulse produced in the motor strip of the cerebral cortex. This impulse is transmitted along the spinal cord to the cell body of the motor nerve.

Spinal Reflexes

Within the spinal cord are cells with short fibers that connect the sensory nerves with the motor

nerves. These are direct connections bypassing the brain. These cells are where spinal reflexes occur. In addition, these cells allow sensory and motor impulses to transmit from one nerve to another within the CNS.

Words of Wisdom

In the brainstem, most nerves cross from one side to the other. Motor and sensory nerves on the left side of the brain, for example, serve the right side of the body. Therefore, a person who has experienced a stroke or sustained trauma in one hemisphere has nerve deficits on the opposite side of the body. Because the cranial nerves are above this crossover point, their function will be affected on the same side of the face as the injury or stroke.

An irritating stimulus to the sensory nerve, such as heat, will be transmitted from the sensory nerve along the connecting nerve directly to the motor nerve. This will stimulate the motor nerve. The muscle responds promptly, withdrawing the limb from the irritating stimulus even before this information can be transmitted to the brain. Technically, you do not “feel” the heat of the fire before you move your hand away. This process is in place to limit damage to the body. When physicians tap your knee with a rubber hammer, they are testing to see whether your reflex arc is intact.

Cranial Nerves

Twelve pairs of **cranial nerves** arise from the base of the brain. All but two pairs, the olfactory nerves and the optic nerves, exit from the brainstem (**FIGURE 7-76**).

Some of the cranial nerves carry only sensory fibers (I, II, and VIII), and others carry only motor fibers (III, IV, VI, XI, and XII). Many are mixed nerves, carrying a combination of sensory fibers and motor fibers (V, VII, IX, and X). Some cranial nerves also carry nerves of the parasympathetic nervous system in combination with motor, sensory, or both types of nerves (III, VII, IX, and X). Each nerve passes from the brain through a foramen in the skull to reach its end point.

The olfactory nerve (I) provides the sense of smell. The optic nerve (II) provides the sense of vision.

FIGURE 7-76 The cranial nerves.

© Jones & Bartlett Learning.

The **oculomotor nerve** (III) innervates the muscles that cause motion of the eyeballs and upper lid. The oculomotor nerve also carries parasympathetic nerve fibers that cause constriction of the pupil (sphincter muscle) and accommodation of the lens (ciliary muscle).

The trochlear nerve (IV) innervates the superior oblique muscle of the eyeball, which allows a downward gaze. The trigeminal nerve (V) supplies sensation to the scalp, forehead, face, and lower jaw via three branches: the ophthalmic, maxillary, and mandibular divisions. The trigeminal nerve also provides motor innervation to the muscles of mastication (chewing), the throat, and the inner ear.

The abducens nerve (VI) supplies the lateral rectus muscle of the eyeball (lateral movement). The facial nerve (VII) supplies motor activity to all muscles of facial expression; the sense of taste to the anterior two-thirds of the tongue; and cutaneous sensation to the external ear, tongue, and palate. The facial nerve also carries parasympathetic stimulation to the salivary glands, lacrimal gland, and the glands of the nasal cavity and palate.

The vestibulocochlear nerve (VIII) passes through the internal auditory meatus and provides the senses of hearing and balance. The glossopharyngeal nerve (IX) supplies motor fibers to the pharyngeal muscles. It provides taste sensation to the posterior portion of the tongue and carries

parasympathetic fibers to the salivary glands (parotid glands) located on each side of the face.

The **vagus nerve** (X) provides motor functions to the soft palate, pharynx, and larynx (voice). The vagus nerve carries sensory fibers from the inferior pharynx, larynx, thoracic, and abdominal organs; taste bud fibers from the posterior tongue; and parasympathetic fibers to thoracic and abdominal organs.

The spinal accessory nerve (XI) provides motor innervation to the muscles of the soft palate and the pharynx and to the sternocleidomastoid and trapezius muscles. The spinal accessory nerve controls swallowing, speech, and head and shoulder movements. The hypoglossal nerve (XII) provides motor function to the muscles of the tongue and throat.

Dermatomes

A **dermatome** is an area of the skin that corresponds to certain spinal nerves (**FIGURE 7-77**). It is helpful to be familiar with dermatomes when assessing for potential spinal cord injury. When a spinal cord injury has occurred, the patient may have impairment in a specific dermatome that translates to impairment distal to a certain nerve or vertebra.

The Eye

The cranial nerves connect the body's senses to the brain. The eye and other senses provide a multitude

FIGURE 7-77 Dermatome map showing the association of the spinal nerves and the cutaneous areas of the body.

© Jones & Bartlett Learning.

of information to the brain for it to process to understand the world around us.

The eyeball is called the globe. The inner surface of the eyelids and the exposed surface of the eye itself, which are covered by a delicate membrane, the **conjunctiva**, are kept moist by fluid produced by the **lacrimal glands**, often called tear glands. Humans blink unconsciously many times per minute. This action sweeps fluid from the lacrimal glands over the surface of the eye, cleaning it. The tears drain on the inner side of the eye through two lacrimal (tear) ducts into the nasal cavity. This is why, when people cry, they sometimes need to blow their nose.

Behind the **iris** is the **lens**. Like the lens of a camera, this lens focuses images on the light-sensitive area at the back of the globe, called the **retina**. Within the retina are numerous nerve endings, which respond to light by transmitting nerve impulses through the **optic nerve** to the brain. In the brain, the impulses are interpreted as vision. There are two types of vision. **Central vision** facilitates visualization of objects directly in front of you and is processed by the macula, the central portion of the retina. The remainder of the retina processes **peripheral vision**, which allows visualization of lateral objects while you are looking forward.

The retina is nourished by a layer of blood vessels (the choroid) between it and the sclera at the back of the globe. If the retina becomes detached from the underlying choroid and sclera, the nerve endings are not nourished, and the patient experiences blindness. The extent of the blindness (partial versus complete) depends on how much of the retina is separated. A detached retina is sometimes surgically treatable.

The Integumentary System (Skin): Anatomy

The **integumentary system** is the largest system in the human body and serves as the interface between the body and the outside world. Human skin is a complex organ that plays a crucial role in maintaining the constancy of the internal environment (homeostasis). It protects tissue from injury, helps regulate body temperature, prevents excessive water loss, and serves as a sense organ. Substantial damage to the skin may leave the body vulnerable to bacterial invasion, temperature instability, and major disturbances of fluid balance.

FIGURE 7-78 The skin has two principal layers: the epidermis and the dermis. Below the skin is a layer of subcutaneous tissue.

© Jones & Bartlett Learning.

The skin is divided into two parts: the superficial **epidermis**, which is composed of several layers of cells and is the body's first line of defense, and the deeper **dermis**, which is a tough, highly elastic layer of connective tissues. Below the skin lies the **subcutaneous tissue** layer, which consists mainly of fat (**FIGURE 7-78**).

The cells of the epidermis are sealed to form a watertight protective covering for the body. The epidermis varies in thickness in different areas of the body. On the soles of the feet, the back, and the **scalp**, it is quite thick, but in some areas of the body, the epidermis is only two or three cell layers thick. The epidermis is composed of several layers of cells. These layers can be separated into two regions. At the base of the epidermis is the **germinal layer**, which continuously produces new cells that gradually rise to the surface. On the way to the surface, these cells die and enter the **stratum corneal layer**. This is the dead layer of skin. Whereas the germinal layer has a blood supply, the stratum corneal layer does not. The journey from the germinal layer to the surface takes approximately 4 weeks. The outermost cells of the epidermis are constantly rubbed away and replaced by new cells produced by the germinal layer. Deeper cells in the germinal layer contain pigment (melanin) granules. Along with blood vessels in the dermis, these granules produce skin color.

Below the germinal layer is the dermis. It is composed chiefly of collagen fibers, elastic fibers, and a

mucopolysaccharide gel. Numerous fibroblasts—cells that secrete collagen, elastin, and ground substance—are found within the dermis. These substances provide resistance to skin breakage and elasticity. Within the dermis lie many of the special structures of the skin: sweat glands, sebaceous (oil) glands, hair follicles, blood vessels, lymph vessels, and specialized nerve endings.

Dilation of vessels in the dermis assists with thermoregulation by increasing blood flow to the skin, allowing heat to dissipate. Conversely, blood vessel constriction results in retention of heat. Macrophages and lymphocytes are also found within the dermal layer. They are responsible for combating microorganisms that breach the epidermal layer.

Sweat glands produce sweat for cooling the body. The sweat is discharged onto the surface of the skin through small pores, or ducts, that pass through the epidermis. The sebaceous glands produce sebum, the oily material that seals the surface epidermal cells. The **sebaceous glands** lie next to hair follicles and secrete sebum along the hair follicle to the skin surface. In addition to providing waterproofing for the skin, sebum keeps the skin soft so it does not crack.

Hair follicles are the small organs that produce hair. The hair grows from the follicle along a shaft until it reaches the epidermal surface. A sebaceous gland is located along the hair shaft. Connected

to the hair is a small muscle. The muscle pulls the hair into an erect position when a person is cold or frightened. Hair goes through stages of growth and rest. Blood vessels provide nutrients and oxygen to the skin. The blood vessels lie in the dermis. Small branches extend up to the germinal layer. A complex array of nerve endings also lies in the dermis. These specialized nerve endings are sensitive to environmental stimuli; they respond to these stimuli and send impulses along the nerves to the brain.

Between the dermis and the underlying muscle and bone is a thick layer of connective tissue known as subcutaneous tissue, or the superficial fascia. This subcutaneous tissue is composed of adipose tissue and areolar tissue. Blood vessels, lymph vessels, and hair follicle roots are also found in this layer (as well as the dermis). The subcutaneous tissue insulates, protects, and stores energy in the form of fat. Subcutaneous injections are given in this layer.

Below the subcutaneous tissue is a thick, dense layer of fibrous tissue known as the **deep fascia**. The deep fascia is composed of tough bands of tissue that surround muscles and other internal structures. It supports and protects underlying structures from injury. Muscles and bones are found below this layer.

The skin covers the entire external surface of the body. The various orifices—including the mouth, nose, anus, and vagina—are not covered by skin. Orifices are lined with mucous membranes. **Mucous membranes** are similar to skin in that they provide a protective barrier against bacterial invasion. Mucous membranes differ from skin in that they secrete **mucus**, a sticky substance that lubricates the openings. Thus, mucous membranes are moist, whereas the skin is dry. For example, a mucous membrane lines the entire digestive tract from the mouth to the anus.

The Integumentary System (Skin): Physiology

The integumentary system serves three major functions: to protect the body in the environment, to regulate the temperature of the body, and to transmit information from the environment to the brain. The protective functions of the skin are numerous. Water makes up a large portion of the body. This water contains a delicate balance of chemical

substances in solution. The skin is watertight and helps keep this balanced internal solution intact. The skin also protects the body from the invasion of infectious organisms: bacteria, viruses, and fungi. These organisms are everywhere and are routinely found lying on the skin surface. However, they never penetrate the skin unless it is broken by injury; thus, the skin provides a constant protection against outside invaders.

The major organ for regulation of body temperature is the skin. Blood vessels in the skin constrict when the body is in a cold environment and dilate when the body is in a warm environment. In a cold environment, constriction of the blood vessels shunts the blood away from the skin to decrease the amount of heat radiated from the body surface. When the outside environment is hot, the vessels in the skin dilate, the skin becomes flushed or red, and heat radiates from the body surface.

Also, in a hot environment, sweat is secreted to the skin surface from the sweat glands. Evaporation of the sweat requires energy. This energy, as body heat, is taken from the body during the evaporation process, which causes the body temperature to fall. Sweating alone will not reduce body temperature; evaporation of the sweat must also occur.

Information from the environment is carried to the brain through a rich supply of sensory nerves that originate in the skin. Nerve endings that lie in the skin are adapted to perceive and transmit information about heat, cold, external pressure, pain, and the position of the body in space. The skin thus recognizes any changes in the environment. The skin also reacts to pressure, pain, and pleasurable stimuli.

The integument responds to injuries and wounds with inflammation, which causes redness, increased warmth, and painful swelling. The blood vessels of the wounded area dilate and allow fluids to leak into the damaged tissues. This provides more nutrients and oxygen to the tissues, aiding in healing.

Words of Wisdom

Considerable damage to the skin may make the body vulnerable to bacterial invasion, temperature instability, and major disturbances of fluid balance, which is precisely what happens when an injury results in an opening in the skin.

Words of Wisdom

The skin, the largest single organ in the body, serves three major functions: to protect the body in the environment, to regulate the temperature of the body, and to transmit information from the environment to the brain.

The Digestive System: Anatomy

The digestive system, also called the gastrointestinal system, is composed of the gastrointestinal tract (stomach and intestines), mouth, salivary glands, pharynx, esophagus, liver, gallbladder, pancreas, rectum, and anus. The function of this system is **digestion**: the processing of food that nourishes the individual cells of the body. The major organs of this system are found within the abdomen.

The Abdomen

The **abdomen** is the second major body cavity; it contains the major organs of digestion and excretion. The diaphragm separates the thoracic cavity

from the abdominal cavity. Anteriorly and posteriorly, thick muscular abdominal walls create the boundaries of this space. Inferiorly, the abdomen is separated from the pelvis by an imaginary plane that extends from the pubic symphysis through the sacrum (**FIGURE 7-79**). Some organs lie in the abdomen and the pelvis, depending on the posture of the patient.

The simplest and most common method of describing the portions of the abdomen is by **quadrants**, the four equal areas formed by two imaginary lines that intersect at right angles at the umbilicus. On the anterior abdominal wall, the quadrants thus formed are the right upper, right lower, left upper, and left lower. The terms *right quadrant* and *left quadrant* refer to the patient's right and left. Pain or injury in a given quadrant usually arises from or involves the organs that lie in that quadrant. This simple means of designation will allow you to identify injured or diseased organs that require emergency attention.

In the right upper quadrant (RUQ), the major organs are the liver, the gallbladder, and a portion of the colon and small intestine. Most of the liver lies in this quadrant, almost entirely under the protection of the 8th to 12th ribs. The liver fills the entire

YOU are the Provider

Part 4

Knowing that time is of the essence in patients such as these, you direct your partner to drive emergently to the local Level I trauma center. Prior to transport you establish an 18-gauge intravenous line to the uninjured arm and infuse fluid at a to-keep-open rate because the systolic blood pressure is above 90 mm Hg, per your local protocols. The patient denies any medical problems or having any known allergies. While en route, you reevaluate your treatments and find that bleeding remains controlled, and the patient's breathing, while still shallow, seems to be improving with the administration of oxygen. You remove the remainder of the patient's clothing and find no additional injuries. On arriving at the trauma center, you turn over care of the patient to the awaiting trauma team.

Recording Time: 14 Minutes

Respirations	14 breaths/min, shallow
Pulse	Weak L radial, 126 via R radial
Skin	Cool, pale, and clammy
Blood pressure	98/58 mm Hg
Oxygen saturation (SpO₂)	97% on 15 L/min
Pupils	PERRLA

- What could be causing the difference in left and right radial pulses in this patient?
- Body fluid is divided into two main compartments. What are they and where are they found?

FIGURE 7-79 The boundaries of the abdomen are the anterior and posterior abdominal cavity walls, the diaphragm, and an imaginary plane from the pubic symphysis to the sacrum. **A.** Anterior view. **B.** Lateral view.

© Jones & Bartlett Learning.

anteroposterior depth of the abdomen in this quadrant. Therefore, injuries in this area are frequently associated with injuries of the liver.

In the left upper quadrant (LUQ), the principal organs are the stomach, the spleen, and a portion of the colon and small intestine. The spleen is almost entirely under the protection of the left rib cage, whereas the stomach may sag well down into the left lower quadrant (LLQ) when full. The spleen lies in the lateral and posterior portion of this quadrant, under the diaphragm and immediately in front of the posterior portion of the 9th to 11th ribs. The spleen is frequently injured, especially when these ribs are fractured.

The right lower quadrant (RLQ) contains two portions of the large intestine: the **cecum**, the first portion into which the small intestine (ileum) opens, and the ascending colon. The **appendix** is a small tubular structure that is attached to the lower border of the cecum. Appendicitis is the most frequent cause of tenderness and pain in this region. In the LLQ lie the descending and the sigmoid portions of the colon.

As mentioned early in this chapter, several organs lie in more than one quadrant. The small intestine, for example, occupies the central part of the abdomen around the umbilicus, and parts of it lie in all four quadrants. The pancreas lies just behind the abdominal cavity on the posterior abdominal wall in

both upper quadrants. The large intestine also traverses the abdomen, beginning in the RLQ and ending in the LLQ as it passes through all four quadrants. The urinary bladder lies just behind the pubic symphysis in the middle of the abdomen and therefore lies in both lower quadrants and also in the pelvis.

The kidneys lie behind the abdominal cavity in the **retroperitoneum**, or space behind the peritoneum (**FIGURE 7-80**). They are above the level of the umbilicus, extending from the 11th rib to the 3rd lumbar vertebra on each side. The kidneys are approximately 5 inches (13 cm) long and lie just anterior to the costovertebral angle.

Mouth

The mouth consists of the lips, cheeks, gums, teeth, and tongue. A mucous membrane lines the mouth. The roof of the mouth is formed by the hard and soft palates. The hard palate is a bony plate lying anteriorly; the soft palate is a fold of mucous membrane and muscle that extends posteriorly from the hard palate into the throat. The soft palate is designed to hold food that is being chewed within the mouth and to help initiate swallowing.

Salivary Glands

There are two **salivary glands** located under the tongue, one on each side of the lower jaw, and one

FIGURE 7-80 The major organs of the retroperitoneal space lie behind the abdominal cavity, above the level of the umbilicus, and extend from the 11th rib to the 3rd lumbar vertebra. Note that the bladder, inferior vena cava, and aorta also lie in this plane.

© Jones & Bartlett Learning.

inside each cheek. These six glands combined produce nearly 1.5 L of saliva daily. Saliva is approximately 98% water. The remaining 2% is composed of mucus, salts, and organic compounds. Saliva serves as a binder for the chewed food that is being swallowed and as a lubricant within the mouth. Saliva also contains certain digestive enzymes.

Oropharynx

The **oropharynx** is a tubular structure that extends vertically from the back of the mouth to the esophagus and trachea. An automatic movement of the pharynx during swallowing lifts the larynx to permit the epiglottis to close over it so that liquids and solids are moved into the esophagus and away from the larynx and trachea.

Esophagus

The esophagus is a collapsible tube about 10 inches (25 cm) long that extends from the end of the pharynx to the stomach and lies just anterior to the spinal column in the chest. Contractions of the muscle in the wall of the esophagus propel food through it to the stomach. Liquids pass with minimal assistance.

Stomach

The stomach is a hollow organ located in the LUQ of the abdominal cavity, largely protected by the

lower left ribs. Muscular contractions in the wall of the stomach and gastric juice, which contains a lot of mucus, convert ingested food to a thoroughly mixed semisolid mass, called **chyme**. The stomach produces approximately 1.5 L of gastric juice daily for this process. The principal function of the stomach is to receive food in large quantities intermittently, store it, and provide for its movement into the small bowel in regular, small amounts. In 1 to 3 hours, the semisolid food mass derived from one meal is propelled by muscular contraction into the duodenum, the first part of the small intestine.

Pancreas

The **pancreas**, a flat, solid organ, lies below and behind the liver and stomach and behind the peritoneum. It is firmly fixed in position, deep within the abdomen, and is not easily damaged. It contains two kinds of glands, and the two portions of the pancreas are intertwined. One portion is exocrine, and it secretes nearly 2 L of pancreatic juice daily. This juice contains many enzymes that aid in the digestion of fat, starch, and protein. Pancreatic juice flows directly into the duodenum through the pancreatic ducts. The other portion of the gland is endocrine. It is called the islets of Langerhans, and this is where insulin is produced. Insulin regulates the amount of glucose in the blood.

Liver

The **liver** is a large, solid organ that takes up most of the area immediately beneath the diaphragm in the RUQ and also extends into the LUQ. It is the largest solid organ in the abdomen and has several functions. Poisonous substances produced by digestion are brought to the liver and rendered harmless. Factors that are necessary for blood clotting and for the production of normal plasma are formed here. Between 0.5 and 1 L of bile is made by the liver daily to assist in the normal digestion of fat. The liver is the principal organ for the storage of sugar or starch for immediate use by the body for energy. It also produces many of the factors that aid in the proper regulation of immune responses. Anatomically, the liver is a large mass of blood vessels and cells, packed tightly together. It is fragile and, because of its size, relatively easily injured. Blood flow in the liver is high, because all of the blood that is pumped to the gastrointestinal tract

passes into the liver, through the portal vein, before it returns to the heart. In addition, the liver has a generous arterial blood supply of its own. Ordinarily, approximately 25% of the cardiac output of blood (1.5 L) passes through the liver each minute.

Bile Ducts

The liver is connected to the intestine by the **bile ducts**. The **gallbladder** is an outpouching from the bile ducts that serves as a reservoir and concentrating organ for bile produced in the liver. Together, the bile ducts and the gallbladder form the biliary system. The gallbladder discharges stored concentrated bile into the duodenum through the common bile duct. The presence of food in the duodenum triggers a contraction of the gallbladder to empty it. The gallbladder usually contains approximately 60 to 90 mL of bile.

Small Intestine

The **small intestine** is the major hollow organ of the abdomen. The cells lining the small intestine produce enzymes and mucus to aid in digestion. Enzymes from the pancreas and the small intestine carry out the final processes of digestion. More than 90% of the products of digestion (amino acids, fatty acids, and simple sugars), together with water, ingested vitamins, and minerals, are absorbed across the wall of the lower end of the small intestine into veins to be transported to the liver. The small intestine is composed of the duodenum, the jejunum, and the ileum. The duodenum, which is approximately 12 inches (30 cm) long, is the part of the small intestine that receives food from the stomach. Here, food is mixed with secretions from the pancreas and liver for further digestion. Bile, produced by the liver and stored in the gallbladder, is emptied as needed into the duodenum. It is green-black, but through changes during digestion, it gives feces its typical brown color. Its major function is in the digestion of fat. The jejunum and ileum together measure more than 20 feet (6 m) on average to make up the rest of the small intestine.

Large Intestine

The **large intestine**, another major hollow organ, consists of the cecum, the colon, and the rectum. Approximately 5 feet (1.5 m) long, it encircles the

outer border of the abdomen around the small bowel. The major function of the colon, the portion of the large intestine that extends from the cecum to the rectum, is to absorb the final 5% to 10% of digested food and water from the intestine to form solid stool, which is stored in the rectum and passed out of the body through the anus.

Appendix

The appendix is a tube 3 to 4 inches (8 to 10 cm) long that opens into the cecum (the first part of the large intestine) in the RLQ of the abdomen. It may easily become obstructed and, as a result, inflamed and infected. Appendicitis, which is the term for this inflammation, is one of the major causes of severe abdominal distress.

Rectum

The lowermost end of the colon is the **rectum**. It is a large, hollow organ that is adapted to store quantities of feces until it is expelled. At its terminal end is the anus, a 2-inch (5-cm) canal lined with skin. The rectum and anus are supplied with a complex series of circular muscles called **sphincters** that control, voluntarily and automatically, the escape of liquids, gases, and solids from the digestive tract. **TABLE 7-11** provides a summary of the organs and functions of the digestive system.

The Digestive System: Physiology

Digestion of food, from the time it is taken into the mouth until essential compounds are extracted and delivered by the circulatory system to nourish all cells in the body, is a complicated chemical process. In succession, different secretions, primarily **enzymes**, are added to the food by the salivary glands, the stomach, the liver, the pancreas, and the small intestine to convert the food into basic sugars, fatty acids, and amino acids. These basic products of digestion are carried across the wall of the intestine and transported through the portal vein to the liver. In the liver, the products are processed further and stored or transported to the heart through veins draining the liver. The heart then pumps the blood with these nutrients throughout the arteries to the capillaries, where the nutrients pass through the capillary walls to nourish the body's individual cells.

TABLE 7-11 Digestive Organs and Functions	
Organ/Structure	Function
Mouth	Mechanically breaks down food; begins chemical breakdown with saliva
Esophagus	Moves food from the mouth to the stomach; muscular and vascular structure
Stomach	Performs mechanical and chemical breakdown of food: food in, chyme out
Small intestine: duodenum, jejunum, and ileum	Major site for chemical breakdown of food; major absorption of water, fats, proteins, carbohydrates, and vitamins
Large intestine	Water absorption; formation of feces; bacterial digestion of food
Anus/rectum	Last portion of large intestine; sphincter to control release of feces
Liver	Production of bile; assists with carbohydrate, protein, and fat metabolism of nutrients within the bloodstream; vitamin storage and manufacture; detoxification of blood; elimination of waste
Pancreas	Exocrine: enzymes for protein, carbohydrate, and fat breakdown within the duodenum Endocrine: insulin and glucagon
Gallbladder	Storage of bile

© Jones & Bartlett Learning.

In normal routine activity, without any food or fluid ingestion at all, between 8 and 10 L of fluid is secreted daily into the gastrointestinal tract. This fluid comes from the salivary glands, stomach, liver, pancreas, and small intestine. In a healthy adult, approximately 7% of the body weight is delivered as fluid daily to the gastrointestinal tract. If substantial vomiting or diarrhea occurs for more than 2 or 3 days, a person will lose a substantial portion of body composition and become severely ill.

The Endocrine System: Anatomy and Physiology

The **endocrine system** is a complex message and control system that integrates many body functions. This system is made up of various glands located throughout the body. **Glands** are cells or organs that remove, concentrate, or alter materials in the blood and then secrete them back into the body.

Exocrine glands (*exo* means “outside”) excrete chemicals for elimination. These glands have ducts that carry their secretions to the surface of the skin or into a body cavity. Sweat glands, salivary glands, and the liver are examples of exocrine glands.

Endocrine glands (*endo* means “inside”) secrete or release chemicals that are used inside the body. These glands lack ducts, so they release hormones directly into the surrounding tissue and blood.

Glands secrete proteins called **hormones** that regulate many body functions, including growth, reproduction, temperature, metabolism, and blood pressure. Endocrine cells and neurosecretory cells manufacture and secrete hormones that are released into the bloodstream and move to their target tissue (**FIGURE 7-81**).

Hormones act on the body’s cells by increasing or decreasing the rate of cellular metabolism. They transfer information from one set of cells to another to coordinate bodily functions, such as the regulation of mood, growth and development, metabolism, tissue function, and sexual development and function.

Hormones, regardless of their source, act by binding to receptors. The nervous system regulates hormone release via nerve impulses. When released into the bloodstream, hormones travel to target tissues. Each target cell has specific receptor sites on the cell membrane, or inside the cell, to which the specific hormone can attach or bind. These receptors have two main functions: to recognize and bind to their particular hormones and to initiate an appropriate signal. Once the hormone has attached to the receptor site of the cell, the “message” to alter the cellular function is delivered.

Many cells contain multiple receptors and act as targets for several hormones—or for molecules introduced into the body as therapy. An **agonist** is a molecule that binds to a cell’s receptor and triggers a response by that cell; agonists produce some kind of action or biologic effect. An **antagonist** is a

FIGURE 7-81 The endocrine system controls the release of hormones in the body.

© Jones & Bartlett Learning.

molecule that binds to a cell's receptor and blocks the action of an agonist. Hormone antagonists are widely used as drugs.

Steroids and thyroid hormones bind to receptors located within cells. All other hormones, as a rule, bind to receptors located on the surface of cells. Hormones stimulate the production of intracellular proteins and other substances that carry out the next task in whichever body process the particular hormone is involved.

The Pituitary Gland and the Hypothalamus

The **pituitary gland** is often referred to as the master gland because its secretions control the secretions of other endocrine glands. It is located at the base of the brain and is about the size of a grape. The hypothalamus is a small region of the brain (not a gland) that regulates the function of the pituitary gland. The hypothalamus is the primary link between the endocrine system and the nervous system. The pituitary is attached to the hypothalamus by a very thin piece of tissue.

The pituitary gland is divided into two portions: the anterior pituitary, which produces and secretes six hormones (growth hormone, thyroid-stimulating hormone, adrenocorticotropic hormone, and three gonadotropic hormones), and the posterior pituitary, which secretes two hormones (ADH and oxytocin) but does not produce them (**FIGURE 7-82**). ADH and oxytocin are synthesized in hypothalamic neurons but are stored in the posterior pituitary gland until the hypothalamus sends nerve signals to the pituitary to release them.

During times of stress, the hypothalamus secretes a hormone that stimulates the anterior pituitary to release **adrenocorticotrophic hormone (ACTH)**. ACTH targets the adrenal cortex and causes it to secrete **cortisol** (a glucocorticoid). Cortisol stimulates most body cells to increase their energy production.

The Thyroid Gland

The large gland at the base of the neck is called the **thyroid gland**. It consists of two lobes that are connected by a narrow band of tissue. The thyroid gland manufactures and secretes hormones that have a role in growth, development, and metabolism.

The thyroid gland secretes **calcitonin**, which helps maintain normal calcium levels in the blood. This hormone is secreted directly into the bloodstream when the thyroid detects high levels of calcium. Calcitonin travels to the bones, where it stimulates the bone-building cells to absorb the excess calcium. It also stimulates the kidneys to absorb and excrete excess calcium.

The Parathyroid Glands

The **parathyroid glands** are embedded in the posterior portion of each lobe of the thyroid. They produce and secrete **parathyroid hormone**, which maintains normal levels of calcium in the blood and normal neuromuscular function. Parathyroid hormone effects are opposite to those of calcitonin.

The Pancreas

The pancreas is an organ of both the endocrine and digestive systems. It produces two hormones, insulin and glucagon, as well as digestive enzymes. The pancreas lies between the greater curvature of the stomach and the duodenum in the

FIGURE 7-82 The pituitary gland secretes hormones from its two regions: the anterior pituitary lobe and the posterior pituitary lobe.

© Jones & Bartlett Learning.

retroperitoneum, or space behind the peritoneum. The head of the pancreas rests near the duodenum; the body and tail of the pancreas project toward the spleen.

In the pancreas, within each islet of Langerhans are **alpha cells** that secrete glucagon, **beta cells** that secrete insulin, and delta cells that secrete somatostatin. Insulin and glucagon perform opposite functions. Insulin causes substances such as sugar, fatty acids, and amino acids to be taken up and metabolized by cells. Insulin also stimulates the storage of unmetabolized food and the conversion of glucose into **glycogen**. Somatostatin is responsible for the inhibition of insulin and glucagon secretion.

Glucagon stimulates the breakdown of glycogen to glucose by a process known as **glycogenolysis**. In addition, glucagon stimulates both the liver and the kidneys to produce glucose from noncarbohydrate molecules by a process known as **gluconeogenesis**. In addition, glucagon activates the breakdown of triglycerides into free fatty acids and glycerol. Depending on the metabolic needs of the body, the free fatty acids and glycerol may be metabolized directly or converted to ketones. In small amounts, ketone

production is normal. In disease states, such as diabetic ketoacidosis, increased plasma glucagon concentrations and unopposed glucagon activity result in excessive production, resulting in possible harm to the patient.

The Adrenal Glands

The **adrenal glands** are located on top of each kidney. The adrenal gland manufactures and secretes certain sex hormones, as well as other hormones that are vital in maintaining the body's water and salt balance. The inner portion of the adrenal glands (the medulla) produces **adrenaline** (also called **epinephrine**), which mediates the fight-or-flight response of the sympathetic nervous system when the body is under stress. The medulla also produces **norepinephrine**. Epinephrine and norepinephrine are vital in the function of the sympathetic nervous system. The remainder of adrenal tissue is known as the **adrenal cortex** (**FIGURE 7-83**).

The adrenal cortex produces hormones called **corticosteroids**, which regulate the body's metabolism, its balance of salt and water, the immune

FIGURE 7-83 The adrenal glands sit on top of the kidney and consist of the adrenal medulla and adrenal cortex.

© Jones & Bartlett Learning.

system, and sexual function. The adrenal medulla produces hormones called **catecholamines** (epinephrine and norepinephrine), which assist the body in coping with physical and emotional stress by increasing the heart and respiratory rates and the blood pressure.

The Reproductive Glands and Hormones

Finally, the endocrine system includes reproductive glands. The **gonads** are the reproductive glands and consist of the **ovaries** in women and the **testes** in men. Testosterone is the major androgen manufactured by the testes. Testosterone also is produced in small amounts in the adrenal glands and in the ovaries. Testosterone is responsible for the development of male secondary sex characteristics, such as a deep voice and facial hair.

The three major female hormones are **estrogen**, **progesterone**, and **human chorionic gonadotropin (hCG)**. The developing embryo in the uterus manufactures hCG if conception takes place to keep the lining of the uterus (endometrium) thick and able to sustain the pregnancy. The ovaries produce estrogen and progesterone. Estrogen functions in the menstrual cycle and in the development of secondary sex characteristics, such as breast development

in adolescence. Progesterone, which is produced by the corpus luteum of the ovary, prepares the uterus for implantation of a fertilized egg. In men, small amounts of estrogen and progesterone also are produced in the testes and adrenal glands.

Excesses or deficiencies in hormone levels cause various diseases. With endocrine diseases, specific body functions are increased, decreased, or absent. Diabetes mellitus is a common problem. Because production of the hormone insulin is deficient, the body is unable to use glucose normally. Insulin is responsible for rapidly moving glucose into cells. Without insulin, glucose moves slowly. This creates a series of complications as the body struggles to find a more readily available fuel for its cells. People with diabetes begin to burn fats and proteins to create the glucose that cells are craving. Interestingly, this results in higher and higher blood glucose levels as glucose accumulates, unable to be moved efficiently into the cells. Chapter 21, *Endocrine and Hematologic Emergencies*, discusses how high blood glucose levels affect the body.

Finally, the pineal gland is an endocrine gland that lies deep in the brain and produces melatonin, which has a role in maintaining circadian rhythm and regulating reproductive hormones.⁵

The Urinary System: Anatomy and Physiology

The **urinary system** controls the discharge of certain waste materials filtered from the blood by the kidneys. In the urinary system, the kidneys are solid organs; the ureters, bladder, and urethra are hollow organs (**FIGURE 7-84**). The main functions of the urinary system are (1) to control fluid balance in the body, (2) to filter and eliminate wastes, and (3) to control pH balance.

The body has two **kidneys** that lie on the posterior muscular wall of the abdomen behind the peritoneum in the retroperitoneal space. These organs rid the blood of toxic waste products and control its balance of water and salt. Blood flow in the kidneys is high. Nearly 20% of the output of blood from the heart passes through the kidneys each minute. Large vessels attach the kidneys directly to the aorta and the inferior vena cava. Waste products and water are constantly filtered from the blood to form urine. The kidneys continuously concentrate this filtered urine by reabsorbing the water as it passes

FIGURE 7-84 The urinary system lies in the retroperitoneal (behind the peritoneum) space behind the organs of the digestive system. The urinary system in males and females includes the kidneys, ureters, bladder, and urethra. This diagram shows the male urinary system.

© Jones & Bartlett Learning.

through a system of specialized tubes within them. The tubes finally unite to form the **renal pelvis**, a cone-shaped collecting area that connects the ureter and the kidney. Normally, each kidney drains its urine into one ureter through which the urine passes to the bladder.

A **ureter** passes from the renal pelvis of each kidney along the surface of the posterior abdominal wall behind the peritoneum to drain into the urinary bladder. The ureters are small (0.2 inch [0.5 cm] in diameter), hollow, muscular tubes. **Peristalsis**, a wavelike contraction of smooth muscle, occurs in these tubes to move the urine to the bladder.

The **urinary bladder** is located immediately behind the pubic symphysis in the pelvic cavity and is composed of smooth muscle with a specialized

lining membrane. The two ureters enter posteriorly at its base on either side. The bladder empties to the outside of the body through the **urethra**. In the male, the urethra passes from the anterior base of the bladder through the penis. In the female, the urethra opens in front of the vagina. A healthy adult forms 1.5 to 2 L of urine every day. This waste is extracted and concentrated from the 1,500 L of blood that circulates through the kidneys daily.

Words of Wisdom

The kidneys also are important in the regulation of the body's fluid balance and blood pressure. They perform these vital functions in conjunction with complex hormone-driven mechanisms. Fluid balance is controlled by the effects of ADH on the kidney. The blood pressure effects are influenced by the **renin-angiotensin system**, of which the kidneys are an important part.

The Genital System: Anatomy and Physiology

The **genital system** controls the reproductive processes by which life is created. The male genitalia, except for the **prostate gland** and the **seminal vesicles**, lie outside the pelvic cavity. The female genitalia, except for the clitoris and labia, are contained entirely within the pelvis. The male and female reproductive organs have certain similarities and, of course, basic differences. They produce sperm and egg cells and reproductive hormones and play an important role in sexual intercourse and reproduction.

The Male Reproductive System and Organs

The male reproductive system consists of the scrotum, testicles, epididymis, vasa deferentia, ejaculatory ducts, urethra, and penis (**FIGURE 7-85**). Each testicle contains specialized cells and ducts; some of these produce male hormones, and others develop sperm. The hormones are absorbed directly into the bloodstream from the testicles. The sperm are immature and are moved from the testicles to the epididymis so they can develop. During ejaculation, the sperm are carried through **vasa deferentia**

FIGURE 7-85 The male reproductive system consists of the testicles, epididymis, vasa deferentia, and penis.

© Jones & Bartlett Learning.

(or vas deferens) to the urethra. Finally, the sperm are deposited by the penis.

The function of the reproductive system is to reproduce. Sperm join with an egg to begin the process of life. In addition to reproduction, this system is also responsible for the production of sex hormones. Many of the physical characteristics of men, such as increased muscle mass, body hair, and deep voice, are attributed to the powerful effects of the hormones released by the testes. Finally, the penis, although part of the reproductive system, is also part of the urinary system. Any damage or infection to the penis can cause problems within the urinary bladder and/or the kidneys.

The Female Reproductive System and Organs

The female reproductive organs include the ovaries, fallopian tubes, uterus, cervix, and vagina (**FIGURE 7-86**). The ovaries (the female reproductive organs) are usually located one on each side of the lower abdominal quadrants. The ovaries, like the testicles, produce sex hormones and specialized cells for reproduction. These hormones regulate

female reproductive function and secondary sexual characteristics such as pubic hair and breast development. The female sex hormones are absorbed directly into the bloodstream.

The ovaries also produce the precursors to mature eggs, the **oocytes**. Within the ovaries, oocytes undergo a maturation process, called **oogenesis**, resulting in production of a specialized **ovum**, a mature egg cell. During the reproductive years of a woman's life, the pituitary gland releases hormones at roughly monthly intervals. These hormones, **follicle-stimulating hormone** and **luteinizing hormone**, stimulate one oocyte to undergo cell division that results in the formation of a mature ovum. A mature ovum is released into one of the fallopian tubes during **ovulation** and is then ready for fertilization by a sperm.

The fallopian tubes are hollow tubes or ducts that extend from the region of each ovary and carry the ovum into the uterus. Once an ovum is inside the fallopian tube, movement of cilia (hairlike projections) on the cell surfaces results in passage of the ovum toward the uterus. The **uterus** is pear-shaped and hollow, with muscular walls. The innermost layer of the uterus, the **endometrium**, is divided into

FIGURE 7-86 The female reproductive system consists of the ovaries, fallopian tubes, uterus, cervix, and vagina.

© Jones & Bartlett Learning.

two layers. The deep basal layer is connected directly to the **myometrium**. The functional layer lines the cavity itself and undergoes menstrual changes and sloughing during the female menstrual cycle. The narrow opening from the uterus to the vagina is the **cervix**. The **vagina** (birth canal) is a muscular distensible tube that connects the uterus with the vulva (the external female genitalia).

The area between the urethral opening and the anus is the **perineum**. It includes skin, the external genitalia, and underlying tissues. Two anatomic triangles make up this area.

The female external genitalia are referred to as the **vulva**. A pair of skin folds, the **labia minora**, borders the vestibule, which is a space into which the vagina and the urethra open. The **clitoris** is located in the anterior margin of the vestibule. It contains erectile tissue which becomes engorged with blood as a result of sexual excitement. The labia minora unite over the clitoris, forming the **prepuce**. Lateral to the labia minora are two prominent, rounded folds of skin, the **labia majora**. These structures unite anteriorly over the pubic symphysis at the **mons pubis**.

During the **menstrual cycle**, an ovum matures, forming a developed ovum. At ovulation, this ovum ruptures through the surface of the ovary. If fertilization occurs, the fertilized egg proceeds through the fallopian tube to implant in the uterus. If fertilization does not occur, a series of hormonal changes causes the remnants of the ovum, called the **corpus**

luteum, to be sloughed, along with the uterine lining. The vagina channels the menstrual flow from the uterus out of the body.

The menstrual cycle is a recurring cycle, beginning at **menarche**, which is the time of the first menstrual cycle, and ending at **menopause**. During each cycle, the lining of the uterus thickens in preparation for pregnancy. If pregnancy does not occur, this functional layer is shed during **menstruation**. The average menstrual cycle is 28 days, with day one being the first day of menstrual flow.

The length of menstruation varies somewhat among women. Various hormones, including gonadotropin-releasing hormone (GnRH), FSH, LH, estrogen and progesterone stimulate the uterine lining at different stages during the menstrual cycle. As mentioned earlier, another hormone involved in reproduction is hCG. It stimulates the corpus luteum to produce progesterone.

The vagina receives the penis during sexual intercourse, when **semen** is deposited in it. Mucous membranes on the surface of the vagina secrete a protective fluid and produce lubricating secretions during sexual intercourse. The sperm in the semen may pass into the uterus and fertilize an egg, causing pregnancy. Should the pregnancy come to completion at approximately 40 weeks, the neonate will pass through the vagina and be born.

Breasts contain the organs of milk production (lactation), the **mammary glands**. Mammary glands are modified sweat glands. In both male and female

breasts, there is an external raised nipple that is surrounded by the pigmented areola. In the female breast, the **areolar glands** produce secretions that protect the nipple and areola during nursing.

The female mammary glands contain 15 to 20 glandular lobes covered by a variable amount of fatty tissue. This superficial fat gives the breast its form. The lobes produce milk, which is stored in and expressed from the nipple.

The functions of the female reproductive system are similar to those of the male reproductive system: reproduction and hormone balance. Urination occurs through the urethra, which in females is not interconnected to the reproductive tract. In males, the urethra is interconnected.

Life Support Chain

The body's cells, tissues, and organs, regardless of their function, all require oxygen, nutrients, and the removal of wastes to perform their job. Oxygen is brought to the cells through the respiratory and circulatory systems. Nutrients are made available to the body after we eat. The digestive system takes the food we eat and breaks it down into glucose, among other things. Glucose is the primary fuel of the body. The circulatory system is the carrier of these supplies and wastes through the process of perfusion. If interference occurs in this delivery system, cells will become damaged or die.

Oxygen is critical for cells; as mentioned earlier, some cells are unable to survive without a constant supply. Most cells in the body can continue to function, even without oxygen, in an anaerobic state for a limited period of time. When illness or injury occurs, the body needs to shift available resources to areas in need while ensuring that critical areas, such as the brain and heart, have an uninterrupted supply of resources. Anaerobic metabolism occurs anytime you exercise vigorously and begin to feel a burning sensation. In this state, limited amounts of energy can be released so the body must quickly correct the oxygen deficiency or risk cellular death. An important by-product of anaerobic metabolism is lactic acid, which is the material that causes muscle burning during anaerobic exercise. Lactic acid is converted back to a useful energy source after oxygen is available. Anaerobic metabolism can be supported in most cells for only 1 to 3 minutes.

Words of Wisdom

When cells function with oxygen, they use aerobic metabolism. They generate large amounts of ATP (cellular energy) and produce wastes of carbon dioxide and water.

When cells function without oxygen, they use anaerobic metabolism. They generate small amounts of ATP (cellular energy) and produce waste as lactic acid.

YOU are the Provider SUMMARY

1. How can knowledge of anatomy and physiology help you care for patients?

Familiarity with the structures and function of the body's systems will allow you to better assess a patient as well as predict potential complications resulting from occult injuries (those not visible to the eye).

2. How can knowledge of medical terminology help you care for patients?

AEMTs must be familiar with the language of topographic anatomy. By using proper medical terms, you will be able to communicate correct information

with the least possible confusion to other members of the health care team.

3. What are the components of the respiratory system?

The respiratory system consists of all the structures of the body that contribute to respiration, or the process of breathing. It includes the nose, mouth, throat, larynx, trachea, bronchi, and bronchioles, which are all air passages or airways. The system also includes the lungs, where oxygen is passed into the blood and carbon dioxide is removed. Finally, the respiratory system includes the diaphragm, the muscles of

YOU are the Provider **SUMMARY** *continued*

the chest wall, and accessory muscles of breathing, which permit normal respiratory movement.

4. On the basis of your knowledge of anatomy, what possible organs may be damaged as a result of the gunshot wound to the abdomen?

In the LUQ, the principal organs are the stomach, the spleen, and a portion of the colon and small intestine. The spleen is almost entirely under the protection of the left rib cage, whereas the stomach may sag well down into the LLQ when full. The spleen lies in the lateral and posterior portion of this quadrant, under the diaphragm and immediately in front of the 9th to 11th ribs. Knowing the anatomic locations of organs and structure will allow you to “picture” possible internal injuries.

5. What are the possible results of respiratory compromise in this patient?

Some possible results of respiratory compromise in this patient include the inability to exhale effectively, resulting in an increase of carbon dioxide in the blood, and the inability to inhale effectively, which causes oxygen levels in the blood to fall. In both situations, the diffusion of respiratory gases will be affected.

6. What type of shock is this patient most likely experiencing?

This patient is most likely experiencing hypovolemic shock, which is a result of loss of circulating volume. Shock is a condition in which organs and tissues

are not receiving an adequate flow of blood and oxygen, or perfusion. A patient in shock has difficulty transporting oxygen in the blood, which allows the buildup of wastes. There are several ways a disease can affect tissue perfusion. Essentially, the patient can have insufficient blood volume or a heart that does not pump effectively, or the patient’s body can no longer control the blood vessels.

7. What could be causing the difference in left and right radial pulses in this patient?

The differences in left and right radial pulses are most likely explained by his gunshot wound to the arm. If the projectile severed a major artery, the patient may have diminished circulation to that arm, creating the difference in pulses.

8. Body fluid is divided into two main compartments. What are they and where are they found?

Body fluid is divided into two main compartments: intracellular and extracellular fluid. ICF is found within individual cells and makes up approximately 75% of all body fluid. ECF is the fluid found outside of cell membranes and makes up approximately 25% of all body fluid. ECF is further divided into intravascular fluid and interstitial fluid. Intravascular fluid (plasma), the fluid portion of blood, is noncellular and is found within the blood vessels. Interstitial fluid is the fluid located outside of the blood vessels, in the spaces between the body’s cells. There is a delicate balance among the various fluid compartments of the body that is essential in maintenance of homeostasis.

EMS Patient Care Report (PCR)

Narrative

EMS dispatched to above location for reported shooting. En route, dispatch advised law enforcement on scene with one patient, multiple gunshot wounds. Patient present AO × 4, ABCs intact, lying left lateral on ground, covered in blood. States he heard 5–6 shots, but unsure of how many times he was hit. Manual stabilization provided. Rapid exam reveals GSW to left chest, left upper arm, and left upper abdominal quadrant. Chief complaint difficulty breathing. Bleeding controlled via direct pressure and dressings. Chest wound covered with occlusive dressing. 15 L/min via nonrebreathing mask applied. Secured patient to stretcher, loaded into ambulance. 18-gauge IV line established to right arm, with NS TKO due to patient's blood pressure. Clothing removed, no other injuries found. On arrival at Charity hospital, care and report given to ED staff without incident.

End of report

Prep Kit

Ready for Review

- To properly care for your patients, you must have a thorough understanding of human anatomy and physiology so you can assess the patient's condition and communicate with hospital personnel and other health care providers.
- Cells are the basic functional unit of the body. The cells of the body are extremely varied in their shape and function. Cells with a common job are grouped closely together and are called tissues. Groups of tissues that all perform interrelated jobs form organs. A series of organs working together make up the body systems.
- Cells have a cell membrane, a nucleus, and cytoplasm. Specialized structures within the cell, called organelles, perform specific functions.
- The life cycle of a cell includes interphase, cell division, cytoplasmic division, and differentiation.
- Cellular respiration is the process by which cells use glucose and oxygen to release energy. This process requires three reactions: glycolysis, the Krebs cycle, and the electron transport chain.
- Cell transport mechanisms relate to fluid administration, an AEMT skill. The cell membrane allows some substances to pass through it, but not others. Selective permeability allows normal differences in concentrations between intracellular and extracellular environments to be maintained.
- Several mechanisms, such as diffusion, osmosis, facilitated diffusion, active transport, endocytosis, and exocytosis, allow material to pass through the cell wall.
- Fluid balance in the body must be maintained (homeostasis). Fluid balance is the process of maintaining homeostasis through equal intake and output of fluids. The major mechanisms for maintaining homeostasis include antidiuretic hormone, thirst, kidneys, and water shifts.
- You must be able to identify superficial landmarks of the body and know what lies

underneath the skin so that you can perform an accurate patient assessment.

- The skeleton gives the body its recognizable human form through a collection of bones, ligaments, tendons, and cartilage.
- The skeletal system provides protection for fragile organs, allows for movement, and gives the body its shape.
- The contraction and relaxation of the musculoskeletal system gives the body its ability to move.
- Smooth muscle, also called involuntary muscle, is found within blood vessels and intestines and controls involuntary functions. Skeletal muscle, so named because it attaches to the bones of the skeleton, forms the major muscle mass of the body. It is also called voluntary muscle, because all skeletal muscle is under direct voluntary control.
- Cardiac muscle is different from skeletal and smooth muscle because it has the property of automaticity: it can generate and conduct electricity, and therefore muscular contraction, without influence from the brain.
- The respiratory system consists of all the structures of the body that contribute to the process of breathing. It includes the nose, mouth, throat, larynx, trachea, bronchi, and bronchioles.
- The primary function of the respiratory system is to conduct respiration. Oxygen is essential for the body to function. Gas exchange of oxygen into the blood and carbon dioxide out of the blood occurs at the lungs' alveoli via diffusion.
- Ventilation is the process of moving air in and out of the lungs.
- The respiratory center in the brainstem controls breathing. Nerves in this area sense the level of carbon dioxide in the blood and spinal fluid. The brain adjusts breathing as needed if the level of carbon dioxide or oxygen in the arterial blood is too high or too low.
- Increases in the level of carbon dioxide in the blood (Paco_2) cause decreased pH levels in the respiratory center, which triggers an increase in ventilation. Decreases in the Paco_2 result in increased pH levels in the respiratory center and a decrease in ventilation.
- Hypoxic drive is a backup system the body uses to control respiration. Areas in the brain, walls of the aorta, and carotid arteries act as oxygen sensors and stimulate breathing if the oxygen level falls.
- The concentration of hydrogen ions (H^+) determines the level of acidity in the blood. Normal homeostatic functions keep the concentration of H^+ within a fairly narrow range. pH is the most common expression of acidity. pH ranges from 0 (most acidic) to 14 (most basic), with 7.0 being neutral. When pH is higher than this, the blood is too basic, or alkalotic. When pH is lower, the blood is too acidic, or acidotic.
- The circulatory system is a complex arrangement of connected tubes, including the arteries, arterioles, capillaries, venules, and veins. The cardiac cycle begins with myocardial contraction and concludes at the beginning of the next contraction. The heart's contraction results in pressure changes within the cardiac chambers, resulting in the movement of blood from areas of high pressure to areas of low pressure.
- Blood pressure is noted as a fraction, with the systolic reading placed above the diastolic reading (for example, 140/70 mm Hg).
- The pressure in the aorta against which the left ventricle must pump blood is called the afterload. The greater the afterload, the harder it is for the ventricle to eject blood into the aorta. This reduces the stroke volume—the amount of blood ejected per contraction.
- Cardiac output is the amount of blood pumped through the circulatory system in 1 minute. Cardiac output is expressed in liters per minute (L/min). The cardiac output equals the heart rate multiplied by the stroke volume.
- Increased venous return to the heart stretches the ventricles, resulting in increased cardiac contractility. This relationship is known as the Starling law.
- The nervous system is perhaps the most complex organ system within the human body. It consists of the brain, spinal cord, and nerves.

- The skin is divided into two parts: the superficial epidermis, which is composed of several layers of cells, and the deeper dermis, which contains the specialized skin structures.
- The skin, the largest single organ in the body, serves three major functions: to protect the body in the environment, to regulate the temperature of the body, and to transmit information from the environment to the brain.
- The digestive system comprises the gastrointestinal tract (stomach and intestines), mouth, salivary glands, pharynx, esophagus, liver, gallbladder, pancreas, rectum, and anus.
- Digestion of food, from the time it is taken into the mouth until essential compounds are extracted and delivered by the circulatory system to nourish all cells in the body, is a complicated chemical process.
- The endocrine system is a complex message and control system that integrates many body functions.
- The urinary system controls the discharge of certain waste materials filtered from the blood by the kidneys.
- The genital system controls the reproductive processes by which life is created.

Vital Vocabulary

abdomen The body cavity that contains the major organs of digestion and excretion. It is located below the diaphragm and above the pelvis.

acetabulum The depression on the lateral pelvis where its three component bones join, in which the femoral head fits snugly.

acid A substance that increases the concentration of hydrogen ions in a solution.

acidosis A pathologic condition that results from the accumulation of acids in the body; an increase in extracellular H^+ ions; a blood pH of less than 7.35.

acromioclavicular (AC) separation One or more torn ligaments in the acromioclavicular joint, resulting in a separated shoulder.

acromion process The tip of the shoulder and the site of attachment for the clavicle and various shoulder muscles.

active transport A method used to move compounds across a cell membrane to create or maintain an imbalance of charges.

adenosine triphosphate (ATP) The nucleotide involved in energy metabolism; used to store energy.

adrenal cortex The outer layer of the adrenal gland; it produces hormones that are important in regulating the water and salt balance of the body.

adrenal glands Endocrine glands located on top of the kidneys that release adrenaline when stimulated by the sympathetic nervous system.

adrenaline Hormone produced by the adrenal glands that mediates the “fight-or-flight” response of the sympathetic nervous system; also called epinephrine.

adrenocorticotropic hormone (ACTH) Hormone that targets the adrenal cortex to secrete cortisol (a glucocorticoid).

aerobic metabolism The metabolism that takes place in the presence of oxygen.

afterload The pressure in the aorta against which the left ventricle must pump blood; increasing this pressure can decrease cardiac output.

agonist A substance that mimics the actions of a specific neurotransmitter or hormone by binding to the specific receptor of the naturally occurring substance.

agranulocytes Leukocytes that lack granules.

alkalosis A pathologic condition resulting from the accumulation of bases in the body; a decrease in extracellular H^+ ions; a blood pH greater than 7.45.

alpha cells Cells located in the islets of Langerhans that secrete glucagon.

alpha effects Stimulation of alpha receptors that results in vasoconstriction.

alveolar ducts Ducts formed from division of the respiratory bronchioles in the lower airway; each duct ends in clusters known as alveoli.

alveoli The air sacs of the lungs in which the exchange of oxygen and carbon dioxide takes place.

anaerobic metabolism The metabolism that takes place in the absence of oxygen; the principal product is lactic acid.

anatomy The study of the structure of an organism and its parts.

antagonist A substance that counteracts the action of something else; a drug of this type has an affinity for a cell receptor and, when it binds to that receptor, the cell is prevented from responding.

antibody A protein secreted by certain immune cells that bind antigens to make them more visible to the immune system; an immunoglobulin.

antigen An agent that, when taken into the body, stimulates the formation of specific protective proteins called antibodies.

aorta The main artery that receives blood from the left ventricle and delivers it to all the other arteries that carry blood to the tissues of the body.

aortic arch One of the three described portions of the aorta; the section of the aorta between the ascending and descending portions that gives rise to the right brachiocephalic (innominate), left common carotid, and left subclavian arteries.

aortic valve The one-way, semilunar valve that lies between the left ventricle and the aorta; keeps blood from flowing back into the left ventricle after the left ventricle ejects its blood into the aorta and is one of four heart valves.

appendicular skeleton The portion of the skeletal system that comprises the arms, legs, pelvis, and shoulder girdle.

appendix A small tubular structure that is attached to the lower border of the cecum in the lower right quadrant of the abdomen.

arachnoid The middle membrane of the three meninges that enclose the brain and spinal cord.

areolar glands The glands that produce secretions that protect the nipple and areola during nursing.

arteries Vessels of the circulatory system that carry oxygenated blood away from the heart.

arterioles The smallest branches of arteries leading to the vast network of capillaries.

ascending aorta The first of three portions of the aorta; originates from the left ventricle and gives rise to two branches, the right and left main coronary arteries.

atlanto-occipital joint The location where the atlas articulates with the occipital condyles.

atlas The first cervical vertebra (C1), which provides support for the head.

atrioventricular (AV) node The site located in the right atrium adjacent to the septum that is responsible for transiently slowing electrical conduction.

atrioventricular valves The two valves through which blood flows from the atria to the ventricles.

atrium One of two (right and left) upper chambers of the heart.

atrophy A decrease in cell size as a result of a loss of subcellular components.

auditory ossicles The bones that function in hearing and are located deep within cavities of the temporal bone.

autonomic nervous system The part of the nervous system that regulates functions that are not controlled consciously, but rather involuntarily, such as heart rate, blood pressure, digestion, and sweating.

axial skeleton The part of the skeleton comprising the skull, spinal column, and rib cage.

axillary vein The vein that is formed from the combination of the basilic and cephalic veins; it drains into the subclavian vein.

axis The second cervical vertebra (C2); the point that allows the head to turn.

ball-and-socket joint A joint that allows internal and external rotation, as well as bending.

baroreceptors Receptors in the blood vessels, kidneys, brain, and heart that respond to changes in pressure in the heart or main arteries to help maintain homeostasis.

base A substance that decreases the concentration of hydrogen ions.

basilic vein One of the two major veins of the arm; it combines with the cephalic vein to form the axillary vein.

basophils White blood cells that work to produce chemical mediators during an immune response.

beta cells Cells located in the islets of Langerhans that secrete insulin.

beta effects Stimulation of beta receptors that results in inotropic, dromotropic, and chronotropic states.

biceps The large muscle that covers the front of the humerus.

bile ducts The ducts that convey bile between the liver and the intestine.

bilirubin A waste product of red blood cell destruction that undergoes further metabolism in the liver.

blood The fluid that is pumped by the heart through the arteries, veins, and capillaries and consists of plasma and formed elements or cells, such as red blood cells, white blood cells, and platelets.

blood pressure The pressure that the blood exerts against the walls of the arteries as it passes through them.

bone marrow A substance that manufactures most red blood cells.

brachial artery The major vessel in the upper extremity that supplies blood to the arm.

brain The controlling organ of the body and center of consciousness; functions include perception, control of reactions to the environment, emotional responses, and judgment.

brainstem The area of the brain between the spinal cord and cerebrum, surrounded by the cerebellum; controls functions that are necessary for life, such as respiration and cardiac system functions.

bronchioles Fine subdivisions of the bronchi made of smooth muscle that give rise to the alveolar ducts.

bronchospasm Constriction of the airway passages of the lungs that accompanies muscle spasms.

bruit An abnormal “whooshing” sound indicating turbulent blood flow within a blood vessel.

buffer A substance or group of substances that controls the hydrogen levels in a solution.

buffer system Fast-acting defenses for acid-base changes, providing almost immediate protection against changes in the hydrogen ion concentration of extracellular fluid.

bundle of His Part of the conduction system of the heart; a continuation of the atrioventricular node.

bursa A small fluid-filled sac located between a tendon and a bone that cushions and protects the joint.

calcitonin A hormone produced by the parafollicular cells of the thyroid gland that is important in the regulation of calcium levels in the body.

cancellous bone A type of bone that consists of a lacy network of bony rods called trabeculae.

capillaries Microscopic, thin-walled blood vessels between the arterioles and venules through which oxygen, carbon dioxide, nutrients, and waste products are exchanged between body tissues and the blood.

cardiac cycle The repetitive pumping process that begins with the onset of cardiac muscle contraction and ends just before the beginning of the next contraction.

cardiac muscle The heart muscle.

cardiac output The amount of blood pumped by the heart per minute; calculated by multiplying the stroke volume by the pulse rate per minute.

carotid artery The major artery that supplies blood to the head and brain.

carpometacarpal joint The joint between the wrist and the metacarpal bones; the thumb joint.

cartilage The support structure of the skeletal system that provides cushioning between bones; also forms the nasal septum and portions of the outer ear.

catecholamines Hormones produced by the adrenal medulla (epinephrine and norepinephrine) that assist the body in coping with physical and emotional stress by increasing the heart and respiratory rates and the blood pressure.

cecum The first part of the large intestine, into which the ileum opens.

cell membrane The cell wall; the cell membrane is selectively permeable.

cellular respiration A biochemical process resulting in the production of energy in the form of adenosine triphosphate.

central nervous system (CNS) The brain and spinal cord.

central vision The visualization of objects directly in front of you.

cerebellum One of the three major subdivisions of the brain, sometimes called the athlete's brain; coordinates the various activities of the brain, particularly fine body movements.

cerebrospinal fluid (CSF) Fluid produced in the ventricles of the brain that flows in the subarachnoid space and bathes the meninges.

cerebrum The largest part of the three subdivisions of the brain, sometimes called the gray matter; made up of several lobes that control movement, hearing, balance, speech, visual perception, emotions, and personality.

cervical spine The portion of the spinal column consisting of the first seven vertebrae that lie in the neck.

cervix The lower third, or neck, of the uterus.

chemoreceptors Receptors in the blood vessels, kidneys, brain, and heart that respond to changes in chemical composition of the blood to help maintain homeostasis.

chordae tendineae Thin bands of fibrous tissue that attach to the valves in the heart and prevent them from inverting, preventing regurgitation of blood through the valves from the ventricles to the atria.

choroid plexus Specialized cells within hollow areas in the ventricles of the brain that produce cerebrospinal fluid.

chromosomes Structures formed from condensed fibers and protein of deoxyribonucleic acid; they are threadlike and are contained within the nucleus of the cells.

chronic obstructive pulmonary disease (COPD) A slow, progressive, degenerative, irreversible

disease of the airway that causes destructive changes in the alveoli and bronchioles in the lungs.

chronotropic state Related to the control of the heart's rate of contraction.

chyme The name of the substance that leaves the stomach; a combination of eaten foods with added stomach acids.

circulatory system The complex arrangement of connected tubes, including the arteries, arterioles, capillaries, venules, and veins, that moves blood, oxygen, nutrients, carbon dioxide, and cellular waste throughout the body.

circumflex coronary arteries One of the two branches of the left main coronary artery.

clavicle The collarbone; it is lateral to the sternum and anterior to the scapula.

clitoris Located in the anterior margin of the vestibule and partially hidden by the labia minora, it contains erectile tissue that becomes engorged with blood as a result of sexual excitement.

coccyx The last three to five vertebrae of the spine; the tailbone.

concentration gradient The natural tendency for substances to flow from an area of higher concentration to an area of lower concentration, either within the cell or outside the cell.

conduction system A group of complex electrical tissues within the heart that initiate and transmit stimuli that result in contractions of myocardial tissue.

conjunctiva The delicate membrane that lines the eyelids and covers the anterior exposed surface of the eye.

contractility The strength of heart muscle contraction.

cornea The transparent tissue layer in front of the pupil and iris of the eye.

coronary arteries Arteries that arise from the aorta shortly after it leaves the left ventricle and supply the heart with oxygen and nutrients.

coronary sinus The end of the great cardiac vein that collects blood returning from the walls of the heart.

corpus luteum The remnants of an unfertilized ovum that are sloughed during menstruation.

corticosteroids Any of several steroids secreted by the adrenal gland.

cortisol A hormone that stimulates most body cells to increase their energy production.

cranial nerves The 12 pairs of nerves that arise from the base of the brain.

cranial vault The bones that encase and protect the brain, including the parietal, temporal, frontal, occipital, sphenoid, and ethmoid bones.

cranium The area of the head above the ears and eyes; the skull. The cranium contains the brain.

crenation Shrinkage of a cell that results when too much water leaves the cell through osmosis.

cribriform plate A horizontal bone perforated with numerous foramina for the passage of the olfactory nerve filaments from the nasal cavity.

cricoid cartilage A firm ridge of cartilage that forms the lower part of the larynx.

cricothyroid membrane A thin sheet of fascia that connects the thyroid and cricoid cartilages that make up the larynx.

crista galli A prominent bony ridge in the center of the anterior fossa to which the meninges are attached.

cytokinesis The division of the cytoplasm of a cell.

dead space Any portion of the airway that does contain air and cannot participate in gas exchange, such as the trachea and bronchi.

deep fascia A dense layer of fibrous tissue below the subcutaneous tissue; composed of tough bands of tissue that surround muscles and other internal structures.

dermatome An area of the skin supplied by a specific sensory spinal nerve.

dermis The inner layer of the skin, containing hair follicles, sweat glands, sebaceous glands, nerve endings, and blood vessels.

descending aorta One of the three portions of the aorta, it is the longest portion and extends through the thorax and abdomen into the pelvis.

diapedesis A process whereby leukocytes leave blood vessels to move toward tissue where they are needed most.

diaphragm A muscular dome that forms the undersurface of the thorax, separating the chest from the abdominal cavity. Contraction of the diaphragm (and the chest wall muscles) brings air into the lungs. Relaxation allows air to be expelled from the lungs.

diastole The relaxation, or period of relaxation, of the heart, especially of the ventricles.

diencephalon Portion of the brain between the brainstem and cerebrum; contains the epithalamus, the thalamus, the hypothalamus, and the subthalamus.

diffusion The movement of solutes (molecules) from an area of higher concentration to an area of lower concentration.

digestion The processing of food that nourishes the individual cells of the body.

dorsal respiratory group (DRG) A portion of the medulla oblongata where the primary respiratory pacemaker is found.

dorsalis pedis artery The artery on the anterior surface of the foot between the first and second metatarsals.

dromotropic state Related to the control of the heart's conduction rate.

dura mater The outermost layer of the three meninges that enclose the brain and spinal cord; the toughest meningeal layer.

ejection fraction The portion of the blood ejected from the ventricle during systole.

electrolytes Charged atoms or compounds that result from the loss or gain of an electron. These are ions that the body uses to perform certain critical metabolic processes.

endocardium The thin membrane lining the inside of the heart.

endocrine glands Glands that secrete or release chemicals that are used inside the body.

endocrine system The complex message and control system that integrates many body functions, including the release of hormones.

endometrium The innermost layer of the uterine wall.

endosteum A layer that lines the inner surfaces of bone.

enzymes Substances designed to speed up the rate of specific biochemical reactions.

eosinophils Leukocytes that may play a role following infection in various areas in the body.

epicardium The layer of the serous pericardium that lies closely against the heart; also called the visceral pericardium.

epidermis The outer layer of skin, which is made up of cells that are sealed together to form a watertight protective covering for the body.

epiglottis A thin, leaf-shaped valve that allows air to pass into the trachea but prevents food and liquid from entering.

epinephrine A substance produced by the body (commonly called adrenaline), and a drug produced by pharmaceutical companies that increases pulse rate and blood pressure; the drug of choice for treating an anaphylactic reaction.

epiphyses The growth plates of a long bone; also called the epiphyseal plates.

erythropoiesis The process by which red blood cells are made.

esophagus A collapsible tube that extends from the pharynx to the stomach; contractions of the muscle in the wall of the esophagus propel food and liquids through it to the stomach.

estrogen A hormone released from the ovaries that stimulates the uterine lining during the menstrual cycle.

exocrine glands Glands that excrete chemicals for elimination.

expiratory reserve volume The amount of air that can be exhaled following a normal exhalation.

extracellular fluid (ECF) Fluid outside of the cell, in which most of the body's supply of sodium is contained.

facilitated diffusion A process whereby a carrier molecule moves substances in or out of cells from areas of higher to lower concentration.

fascia The fiberlike connective tissue that covers arteries, veins, tendons, and ligaments.

femoral arteries The principal arteries of the thigh; continuation of the external iliac arteries. These supply blood to the lower abdominal wall, external genitalia, and legs; can be palpated in the groin area.

femoral head The proximal end of the femur, articulating with the acetabulum to form the hip joint.

femoral vein A continuation of the saphenous vein that drains into the external iliac vein.

femur The thighbone; the longest and one of the strongest bones in the body.

fibrin A white, filamentous protein formed by the action of thrombin on fibrinogen; the protein that polymerizes (bonds) to form the fibrous component of a blood clot.

fibula The long bone on the posterior surface of the lower leg.

filtration A type of diffusion in which water carries dissolved compounds across the cell membrane; commonly used by the kidneys to clean blood.

fluid balance The process of maintaining homeostasis through equal intake and output of fluids.

follicle-stimulating hormone A hormone released from the pituitary gland at roughly monthly intervals that helps to stimulate one oocyte to undergo cell division.

fontanelles Areas where the neonate's or infant's skull bones have not fused together; usually disappear at approximately 18 months of age.

foramen magnum A large opening at the base of the skull through which the brain connects to the spinal cord.

foramen ovale An opening between the two atria that is present in the fetus but usually closes shortly after birth.

foramina Small openings, perforations, or orifices in the bones of the cranial vault.

fossa ovalis A depression between the right and left atria that indicates where the foramen ovale had been located in the fetus.

gallbladder A sac on the undersurface of the liver that collects bile from the liver and discharges it into the duodenum through the common bile duct.

genital system The reproductive system in males and females.

germinal layer The deepest layer of the epidermis where new skin cells are formed.

glands Cells or organs that selectively remove, concentrate, or alter materials in the blood and then secrete them back into the body.

glenoid fossa The part of the scapula that forms the socket in the ball-and-socket joint of the shoulder.

gluconeogenesis A process that stimulates both the liver and the kidneys to produce glucose from noncarbohydrate molecules.

glycogen A long polymer from which glucose is converted in the liver (animal starch).

glycogenolysis The process by which glycogen is broken down and converted to glucose; facilitated by glucagon.

gonads The reproductive glands.

granulocytes Leukocytes that have large cytoplasmic granules that are easily seen with a simple light microscope.

greater trochanter A bony prominence on the proximal lateral side of the thigh, just below the hip joint.

heart A hollow muscular organ that pumps blood throughout the body.

hemoglobin An iron-containing protein within red blood cells that has the ability to combine with oxygen; carries 97% of oxygen.

hemostasis Formation of clots to plug openings in injured blood vessels and stop blood flow; the body's natural blood-clotting mechanism.

heparin A substance found in large amounts in basophils that inhibits blood clotting.

hepatic portal system A specialized part of the venous system that drains blood from the stomach, intestines, and spleen.

hepatic veins The veins into which blood empties after liver cells in the sinusoids of the liver

extract nutrients, filter the blood, and metabolize various drugs.

Hering-Breuer reflex The protective nervous system mechanism that terminates inhalation and prevents lung overexpansion.

hilum The point of entry for the bronchi, vessels, and nerves into each lung.

hinge joints Joints that can bend and straighten but cannot rotate; they restrict motion to one plane.

histamine Chemical substance released by the immune system in allergic reactions that is responsible for many of the symptoms of anaphylaxis, such as vasodilation; increases vascular permeability and tissue inflammation; found in large amounts in basophils.

hormones Substances formed in specialized organs or glands and carried to another organ or group of cells in the same organism; these regulate many body functions, including metabolism, growth, and body temperature.

human chorionic gonadotropin (hCG) A hormone that stimulates the corpus luteum to produce progesterone during the first 8 weeks of gestation.

humerus The supporting bone of the upper arm.

hydrostatic pressure The pressure of water against the walls of its container.

hyoid bone A bone at the base of the tongue that supports the tongue and its muscles.

hyperextension Extension beyond the normal range of motion.

hypertonic Concentration of solute is higher compared with another solution.

hypertrophy An increase in the size of the cells as a result of synthesis of more subcellular components, resulting in an increase in tissue and organ size.

hypothalamus The basal part of the diencephalons; it regulates the function of the pituitary gland.

hypotonic A lower concentration of sodium in a solution than exists in the cell; the increased intracellular osmotic pressure lets water flow into the cell, causing it to swell and possibly burst.

hypoxic drive A backup system that controls respirations by sensing when the oxygen level in the blood falls.

ilium One of three bones that fuse to form the pelvic ring.

inferior vena cava One of the two largest veins in the body; carries blood from the lower extremities and the pelvic and the abdominal organs to the heart.

inotropic state Related to the strength of the heart's contraction.

inspiratory reserve volume The amount of air that can be inhaled after a normal inhalation; the amount of air that can be inhaled in addition to the normal tidal volume.

integumentary system The largest organ system in the body, consisting of the skin and accessory structures (eg, hair, nails, glands).

interatrial septum A membrane that separates the right and left atria.

interstitial fluid The fluid located outside of the blood vessels in the spaces between the body's cells.

interstitial space The space in between the cells.

interventricular septum A thick wall that separates the right and left ventricles.

intracellular fluid (ICF) Fluid within cells in which most of the body's supply of potassium is contained.

intravascular fluid (plasma) The noncellular portion of blood found within the blood vessels; also called plasma.

involuntary muscle A muscle over which a person has no conscious control. It is found in many automatic regulating systems of the body.

iris The muscle and surrounding tissue behind the cornea that dilate and constrict the pupil, regulating the amount of light that enters the eye; pigment in this tissue gives the eye its color.

ischium One of three bones that fuse to form the pelvic ring.

isotonic The same concentration of sodium in a solution as in the cell. In this case, water does not shift, and no change in cell shape occurs.

joint (articulation) The point at which two or more bones articulate, or come into contact.

joint capsule The fibrous sac that encloses a joint.

jugular veins The two main veins that drain the head and neck.

kidneys Two retroperitoneal organs that excrete the end products of metabolism as urine and regulate the body's salt and water content.

labia majora Two prominent, rounded folds of skin lateral to the labia minora of the female external genitalia.

labia minora A pair of skin folds in the female external genitalia that border the vestibule.

labored breathing Breathing that requires greater than normal effort; may be slower or faster than normal and characterized by grunting, stridor, and use of accessory muscles; occurs when air movement is impaired.

lacrimal glands The glands that produce fluids to keep the eye moist; also called tear glands.

lactic acid A metabolic end product of the breakdown of glucose that accumulates when metabolism proceeds in the absence of oxygen.

large intestine The portion of the digestive tube that encircles the abdomen around the small bowel, consisting of the cecum, the colon, and the rectum. It helps regulate water balance and eliminate solid waste.

lateral malleolus An enlargement of the distal end of the fibula, which forms the lateral wall of the ankle joint.

left anterior descending (LAD) artery One of the two branches of the left main coronary artery, which is the largest and shortest of the myocardial blood vessels; this vessel and the circumflex coronary arteries supply blood to the left ventricle and other areas.

lens The transparent part of the eye through which images are focused on the retina.

ligament A band of fibrous tissue that connects bones to bones; supports and strengthens a joint.

limbic system Structures within the cerebrum and diencephalon that influence emotions,

motivation, mood, and sensations of pain and pleasure.

liver A large solid organ that lies in the right upper quadrant immediately below the diaphragm; it produces bile, stores glucose for immediate use by the body, and produces many substances that help regulate immune responses.

lumbar spine The lower part of the back, formed by the lowest five nonfused vertebrae; also called the dorsal spine.

lungs The two primary organs of breathing.

luteinizing hormone A hormone released from the pituitary gland at roughly monthly intervals that helps to stimulate one oocyte to undergo cell division.

lymph A thin, plasmalike liquid formed from interstitial or extracellular fluid that bathes the tissues of the body.

lymph nodes Round or bean-shaped structures interspersed along the course of the lymph vessels, where infection fighting cells are housed, and which filter the lymph and serve as a source of lymphocytes.

lymph vessels Thin-walled vessels through which lymph circulates through the body; they travel close to the major veins.

lymphatic system A passive circulatory system that transports a plasmalike liquid called lymph, a thin fluid that bathes the tissues of the body.

lymphocytes The smallest of the agranulocytes; they originate in the bone marrow but migrate through the blood to the lymphatic tissues.

lysis The process of disintegration, breakdown, or rupturing of cells caused by either the presence of certain enzymes, or from excess water entering the cell through osmosis.

macrophages Cells that are responsible for protecting the body against infection.

main stem bronchi The part of the lower airway below the larynx through which air enters the lungs.

mammary glands The organs of milk production in the breasts.

mandible The bone of the lower jaw.

manubrium The upper fourth of the sternum.

mastoid process A prominent bony mass at the base of the skull behind the ear.

maxillae The upper jawbones that assist in the formation of the orbit, the nasal cavity, and the palate and hold the upper teeth.

medial malleolus The distal end of the tibia, which forms the medial side of the ankle joint.

mediastinum The space between the lungs, in the center of the chest, that contains the heart, trachea, large blood vessels, main stem bronchi, part of the esophagus, lymphatic channels, and paired vagus and phrenic nerves.

medulla oblongata Nerve tissue that is continuous inferiorly with the spinal cord; serves as a conduction pathway for ascending and descending nerve tracts; coordinates heart rate, blood vessel diameter, breathing, swallowing, vomiting, coughing, and sneezing.

medullary cavity An internal cavity that contains bone marrow.

meiosis A type of cell division that occurs in the production of eggs and sperm.

menarche The initial onset of menstruation occurring during puberty; the first menstrual cycle.

meninges A set of three tough membranes, the dura mater, arachnoid, and pia mater, that enclose and protect the entire brain and spinal cord within the skull and the spinal canal.

menopause The cessation of the menstrual cycle and ovarian function.

menstrual cycle A cycle lasting approximately 28 days in which physiologic changes occur in the uterus and associated reproductive organs.

menstruation The period in the menstrual cycle of sloughing and discharge of the functional layer of the endometrium; occurs approximately every 28 days.

metabolic acidosis A pathologic condition characterized by a blood pH of less than 7.35 and caused by accumulation of acids in the body from a metabolic cause.

metabolic alkalosis A pathologic condition characterized by a blood pH of greater than 7.45 and

resulting from the accumulation of bases in the body from a metabolic cause.

metacarpal bones The bones that form the hand.

midbrain The part of the brain that is responsible for helping to regulate the level of consciousness.

minute volume The amount of air moved in and out of the respiratory tract (minus the dead space) per minute; determined by the tidal volume multiplied by the respiratory rate. Also called minute ventilation.

mitosis The division of the nucleus of a cell.

mitral valve The valve in the heart that separates the left atrium from the left ventricle.

monocytes Agranulocytes that migrate out of the blood and into the tissues in response to an infection.

mons pubis The pad of fatty tissue and coarse skin that lies over the pubic symphysis.

motor nerves Nerves that carry information from the central nervous system to the muscles of the body.

mucous membranes The lining of body cavities and passages that communicate directly or indirectly with the environment outside the body.

mucus The opaque, sticky secretion of the mucous membranes that lubricates the body openings.

murmur An abnormal heart sound, heard as a “whooshing” sound, indicating turbulent blood flow within the heart.

musculoskeletal system The bones and voluntary muscles of the body.

myocardial infarction Blockage of the arteries that supply oxygen to the heart, resulting in death to a portion of the myocardium.

myocardium The heart muscle.

myoglobin A pigment synthesized in the muscles to give skeletal muscles their red-brown color.

myometrium A thick smooth muscle that forms the middle layer of the uterine wall.

nasal cavity The chamber inside the nose that lies between the floor of the cranium and the roof of the mouth.

nasal septum The separation between the right and left nostrils.

nasopharynx The part of the pharynx that lies above the level of the roof of the mouth, or palate.

neoplasm A mass of tissue produced by abnormal cell growth and division that may be malignant (cancerous) or benign; a tumor.

nervous system The system that controls virtually all activities of the body, both voluntary and involuntary.

neutrophils One of the three types of granulocytes; they have multilobed nuclei that resemble a string of baseballs held together by a thin strand of thread; they destroy bacteria, antigen-antibody complexes, and foreign matter.

norepinephrine A neurotransmitter and drug sometimes used in the treatment of shock; produces vasoconstriction through its alpha-stimulator properties.

oculomotor nerve The cranial nerve (III) that innervates the muscles that cause motion of the eyeballs and upper eyelid.

olfactory nerve The cranial nerve (I) for smell.

oncotic pressure The pressure of water to move, typically into the capillary, as the result of the presence of plasma proteins.

oocytes Female sex cells; the precursors to a mature egg.

oogenesis The maturation process that results in production of an ovum, or egg.

optic nerve Either of the second cranial nerves that enter the eyeball posteriorly, through the optic foramen, which transmit visual information to the brain.

orbit The eye socket, made up of the maxilla and zygoma.

oropharynx A tubular structure that extends vertically from the back of the mouth to the esophagus and trachea.

osmosis The movement of a solvent (fluid), such as water, from an area of lower solute concentration to one of higher concentration through a selectively permeable membrane to equalize concentrations of a solute on both sides of the membrane.

osmotic pressure Pressure created against the cell wall by the presence of water.

ovaries Glands that lie on either side of the pelvic cavity in a woman and produce sex hormones and ova (eggs).

ovulation The release of a mature egg (ovum) into the fallopian tube from the ovary.

ovum A mature egg released by the ovary during ovulation.

pancreas A flat, solid organ that can also be considered a gland, that lies below the liver and the stomach; it is a major source of digestive enzymes delivered into the duodenum, and produces the hormone insulin; considered both an endocrine gland and an exocrine gland.

papillary muscles Specialized muscles that attach the ventricles to the cusps of the valves by muscular strands called chordae tendineae.

paranasal sinuses The sinuses, or hollowed sections of bone in the front of the head, which are lined with mucous membrane and drain into the nasal cavity.

parasympathetic nervous system A subdivision of the autonomic nervous system, involved in control of involuntary, vegetative functions, mediated largely by the vagus nerve through the chemical acetylcholine; the part of the autonomic nervous system that relaxes the body.

parathyroid glands Four glands that are embedded in the posterior portion of each lobe of the thyroid; they produce and secrete parathyroid hormone.

parathyroid hormone Hormone produced and secreted by the parathyroid glands; it maintains normal levels of calcium in the blood and normal neuromuscular function.

parietal pleura The thin membrane that lines the pleural (chest) cavity.

partial pressure of carbon dioxide (P_{aCO_2}) A measurement of the amount of carbon dioxide in the blood.

partial pressure of oxygen (P_{aO_2}) A measurement of the amount of oxygen in the blood.

patella The kneecap; a specialized bone that lies within the tendon of the quadriceps muscle.

pelvis The attachment of the lower extremities to the body, consisting of the sacrum and two pelvic bones.

perfusion The circulation of oxygenated blood within an organ or tissue in adequate amounts to meet the cells' current needs.

pericardial fluid A serous fluid that fills the space between the visceral pericardium and the parietal pericardium and helps to reduce friction.

pericardium A thick, fibrous membrane that surrounds the heart; also called the pericardial sac.

perineum The area of skin between the scrotum and the anus in males, and the vagina and the anus in females.

periosteum A double layer of connective tissue that lines the outer surface of the bone.

peripheral nervous system (PNS) The 31 pairs of spinal nerves and 12 pairs of cranial nerves that link the body's other organs to the central nervous system; these may be sensory, motor, or connecting nerves.

peripheral vision Visualization of lateral objects while looking forward.

peristalsis The wavelike contraction of smooth muscle by which the ureters or other tubular organs propel their contents.

pH The measure of acidity or alkalinity of a solution.

phalanges The small bones of the digits of the fingers and toes.

physiology The study of the body functions of the living organism.

pia mater The innermost and thinnest of the three meninges that enclose the brain and spinal cord; it rests directly on the brain and spinal cord.

pituitary gland An endocrine gland, located in the sella turcica of the brain, responsible for directly or indirectly affecting all body functions.

plasma A sticky, yellow fluid made mostly of water, but also electrolytes, clotting factors, and glucose, that is a component of blood that carries the blood cells, formed elements, and nutrients and transports cellular waste material to the organs of excretion.

plasmin An enzyme that dissolves the fibrin in blood clots.

platelets Tiny, disk-shaped elements that are much smaller than the cells; they are essential in the initial formation of a blood clot, the mechanism that stops bleeding.

pleura The serous membrane covering the lungs and lining the thoracic cavity, completely enclosing a potential space known as the pleural space.

pleural cavity The potential space between the visceral and parietal pleura.

pleural space Potential space between the visceral and parietal pleura of the lung and chest wall, respectively; it is normally absent, as these surfaces are usually in direct contact.

pneumotaxic (pontine) center A portion of the pons that assists in creating shorter, faster respirations.

pons An organ that lies below the midbrain and above the medulla and contains numerous important nerve fibers, including those for sleep, respiration, and the medullary respiratory center.

popliteal artery A continuation of the femoral artery at the knee.

posterior tibial artery The artery just behind the medial malleolus; supplies blood to the foot.

preload The precontraction pressure in the heart, which increases as the volume of blood builds up when returned to the heart (venous return); directly affects afterload.

prepuce A structure in the female external genitalia that is formed where the labia minora unite over the clitoris.

progesterone A hormone released from the ovaries that stimulates the uterine lining during the menstrual cycle in preparation for implantation of a fertilized egg.

prostate gland A small gland that surrounds the male urethra where it emerges from the urinary bladder; it secretes a fluid that is part of the ejaculatory fluid.

pubic symphysis A hard bony and cartilaginous prominence found at the midline in the lowermost portion of the abdomen where the two

halves of the pelvic ring are joined by cartilage at a joint with minimal motion.

pubis One of three bones that fuse to form the pelvic ring.

pulmonary artery The major artery leading from the right ventricle of the heart to the lungs; it carries oxygen-poor blood.

pulmonary-capillary membrane The very thin membrane, consisting of only one cell layer, that lies between the alveolus and capillary, through which respiratory exchange between the alveolus and the blood vessels occurs.

pulmonary circulation The flow of blood from the right ventricle through the pulmonary arteries and all of their branches and capillaries in the lungs and back to the left atrium through the venules and pulmonary veins; also called the lesser circulation.

pulmonary veins The four veins that return oxygenated blood from the lungs to the left atrium of the heart.

pulmonic valve The semilunar valve that regulates blood flow between the right ventricle and the pulmonary artery.

pulse The wave of pressure created as the heart contracts and forces blood out the left ventricle and into the major arteries.

pulse pressure The difference between the systolic blood pressure and the diastolic blood pressure.

quadrants The four sections of the abdominal cavity shown by two imaginary lines intersecting at the umbilicus, dividing the abdomen into four equal areas.

radius The bone on the thumb side of the forearm.

rectum The lowermost end of the colon.

red blood cells (RBCs) The formed elements in the blood that contain hemoglobin and are responsible for carrying oxygen to the tissues; also called erythrocytes.

renal pelvis A cone-shaped collecting area that connects the ureter and the kidney.

renin-angiotensin system System located in the kidney that helps to regulate fluid balance and blood pressure.

residual volume The air that remains in the lungs after maximal expiration.

respiration The inhaling and exhaling of air; the physiologic process that exchanges carbon dioxide from fresh air.

respiratory acidosis A pathologic condition characterized by a blood pH of less than 7.35 and caused by accumulation of acids in the body from a respiratory cause such as inadequate ventilation.

respiratory alkalosis A pathologic condition characterized by a blood pH of greater than 7.45 and caused by an accumulation of bases in the body from a respiratory cause such as overaggressive ventilation.

respiratory system All the structures of the body that contribute to the process of breathing, consisting of the upper and lower airways and their component parts.

reticular activating system Located in the upper brainstem; responsible for maintenance of consciousness, specifically one's level of arousal.

retina The light-sensitive area of the eye where images are projected; a layer of cells at the back of the eye that changes the light image into electrical impulses, which are carried by the optic nerve to the brain.

retroperitoneum The space behind the peritoneum.

Rh factor An antigen found on the red blood cells of most people; in pregnancy, a woman's body can create antibodies against this, which can be problematic to future pregnancies.

sacroiliac joints The connection points between the pelvis and the vertebral column.

sacrum One of three bones that make up the pelvic ring; consists of five fused sacral vertebrae.

saddle joint Two saddle-shaped articulating surfaces oriented at right angles to each other so that complementary surfaces articulate with each other, such as in the thumb.

salivary glands The glands that produce saliva to keep the mouth and pharynx moist.

saphenous vein The longest vein in the body; it drains the leg, thigh, and dorsum of the foot.

scalp The thick skin covering the cranium, which usually bears hair.

scapula The shoulder blade.

sebaceous glands Glands that produce an oily substance called sebum, which discharges along the shafts of the hairs.

secondary bronchi Airway passages in the lungs that are formed from the division of the right and left main stem bronchi.

semen Seminal fluid ejaculated from the penis and containing sperm.

semilunar valves The two valves, the aortic and pulmonic valves, that divide the heart from the aorta and pulmonary arteries.

seminal vesicles Storage sacs for sperm and seminal fluid, which empty into the urethra at the prostate.

semipermeable Property of the cell membrane that describes the ability to allow certain elements to pass through while not allowing others to do so.

sensory nerves The nerves that transmit sensory input, such as touch, taste, heat, cold, and pain, from the body to the central nervous system.

shock A condition in which the circulatory system fails to provide sufficient circulation to enable every body part to perform its function; also called hypoperfusion.

shoulder girdle The proximal portion of the upper extremity, made up of the clavicle, the scapula, and the humerus.

sinoatrial (SA) node The normal site of the origin of electrical impulses; located high in the right atrium, it is the heart's natural pacemaker.

sinusitis An inflammation of the paranasal sinuses.

skeletal muscle Muscle that is attached to bones and usually crosses at least one joint; striated, or voluntary, muscle.

skeleton The framework that gives the body its recognizable form; also designed to allow motion of the body and protection of vital organs.

skull The structure at the top of the axial skeleton that houses the brain and consists of the 28 bones that comprise the auditory ossicles, the cranium, and the face.

small intestine The portion of the digestive tube between the stomach and the cecum, consisting of the duodenum, jejunum, and ileum.

smooth muscle Involuntary muscle; it constitutes the bulk of the gastrointestinal tract and is present in nearly every organ to regulate automatic activity.

solute A particle, such as salt, that is dissolved in a solvent.

solution A liquid mixture that cannot be separated by filtering or allowing the mixture to stand.

somatic nervous system The part of the nervous system that regulates a person's voluntary activities, such as walking, talking, and writing.

sphincters Circular muscles that surround and, by contracting, constrict a duct, tube, or opening. Examples are found within the rectum, bladder, and blood vessels.

sphygmomanometer A device used to measure blood pressure.

spinal cord An extension of the brain, composed of virtually all nerves carrying messages between the brain and the rest of the body. It lies inside of and is protected by the spinal canal.

Starling law A principle that states that if a muscle is stretched slightly before stimulation to contract, the muscle will contract harder; describes how increased venous return to the heart stretches the ventricles and allows for increased cardiac contractility.

stem cell A type of cell that can develop into other types of cell in the body; this type of cell retains the ability to divide repeatedly without specializing and allows for continual growth and renewal.

sternocleidomastoid muscles The muscles on either side of the neck that allow movement of the head.

sternum The breastbone.

stratum corneal layer The outermost or dead layer of the skin.

striated muscle Muscle that is attached to bones and usually crosses at least one joint; also called skeletal or voluntary muscle.

stroke volume (SV) The volume of blood pumped forward from the left ventricle into the aorta with each ventricular contraction.

subarachnoid hemorrhage A hemorrhage into the subarachnoid space between the arachnoid membrane and the pia mater, where the cerebrospinal fluid circulates.

subarachnoid space The space located between the pia mater and the arachnoid membrane.

subclavian artery The proximal part of the main artery of the arm, which supplies the brain, neck, anterior chest wall, and shoulder.

subclavian veins The proximal part of the main veins of the arm, which unite with the internal jugular veins.

subcutaneous tissue Tissue, largely fat, that lies directly under the dermis and serves as an insulator of the body.

superior vena cava One of the two largest veins in the body; carries blood from the upper extremities, head, neck, and chest into the heart.

surfactant A liquid protein substance that coats the alveoli in the lungs, decreases alveolar surface tension, and keeps the alveoli expanded, allowing for easy expansion and recoil of the alveoli; a low level in a premature baby contributes to respiratory distress syndrome.

sutures Attachment points in the skull where the cranial bones join together.

sweat glands The glands that secrete sweat, located in the dermal layer of the skin.

sympathetic nervous system Subdivision of the autonomic nervous system that governs the body's fight-or-flight reactions by inducing smooth muscle contraction or relaxation of the blood vessels and bronchioles; responsible for the body's response to shock and stress.

symphysis A type of joint that has grown together forming a very stable connection.

synovial fluid The small amount of liquid within a joint used as lubrication.

synovial membrane The lining of a joint that secretes synovial fluid into the joint space.

systemic circulation The circulatory system in the body that is responsible for blood flow in all

areas of the body, except for areas covered by the pulmonary circulation (blood flow from the right side of the heart to the lungs and back to the left side of the heart).

systemic vascular resistance (SVR) The resistance that blood must overcome to be able to move within the blood vessels; related to the amount of dilation or constriction in the blood vessel.

systole The contraction, or period of contraction, of the heart, especially that of the ventricles.

temporomandibular joint (TMJ) The joint where the mandible meets with the temporal bone of the cranium just in front of each ear.

tendon A tough, ropelike cord of fibrous tissue that attaches skeletal muscle to bone.

tertiary bronchi Airway passages in the lungs that are formed from branching of the secondary bronchi.

testes The male reproductive organs that produce sperm and secrete male hormones; also called testicles.

thalamus Structure of the diencephalon that is the sensory switchboard of the brain, through which almost all signals travel on their way in or out of the brain.

thoracic duct One of two great lymph vessels; it empties into the superior vena cava.

thoracic spine The 12 vertebrae that lie between the cervical vertebrae and the lumbar vertebrae. One pair of ribs is attached to each of the thoracic vertebrae.

thorax The chest cavity that contains the heart, lungs, esophagus, and great vessels.

thrombin An enzyme that causes the conversion of fibrinogen to fibrin, which binds to the platelet plug, forming the final mature clot.

thyroid cartilage A firm prominence of cartilage that forms the upper part of the larynx; the Adam's apple.

thyroid gland A large endocrine gland that is located at the base of the neck and produces and excretes hormones that influence growth, development, and metabolism.

tibia The shin bone, the larger of the two bones of the lower leg.

tidal volume The amount of air (in milliliters) that is moved into or out of the lungs during one relaxed breath; approximately 500 mL for an adult.

tissue plasminogen activator (t-PA) A major component in the fibrinolytic system, in which clots that have already formed are lysed or disrupted, converting plasminogen to plasmin.

trabeculae Bony rods that form the lacy network in cancellous bones and are oriented to increase weight-bearing capacity of long bones.

trachea The windpipe; the main trunk for air passing to and from the lungs.

triceps The muscle in the back of the upper arm.

tricuspid valve The heart valve that separates the right atrium from the right ventricle.

tunica adventitia The outer layer of tissue of a blood vessel wall, composed of elastic and fibrous connective tissue.

tunica intima The smooth, thin, inner lining of a blood vessel.

tunica media The middle and thickest layer of tissue of a blood vessel wall, composed of elastic tissue and smooth muscle cells that allow the vessel to expand or contract in response to changes in blood pressure and tissue demand.

ulna The inner bone of the forearm, on the side opposite the thumb.

ureter A small, hollow tube that carries urine from the kidneys to the bladder.

urethra The canal that conveys urine from the bladder to outside the body.

urinary bladder A sac behind the pubic symphysis made of smooth muscle that collects and stores urine.

urinary system The organs that control the discharge of certain waste materials filtered from the blood and excreted as urine.

uterus The muscular, inverted pear-shaped organ that lies situated between the urinary bladder and the rectum, where the fetus grows; also called the womb; responsible for contractions during labor.

vagina The muscular tube that forms the lower part of the female reproductive tract; connects the uterus with the vulva (the external female genitalia); also called the birth canal.

vagus nerve The cranial nerve (X) that provides motor functions to the soft palate, pharynx, and larynx and carries taste bud fibers from the posterior tongue, sensory fibers from the inferior pharynx, larynx, thoracic, and abdominal organs, and parasympathetic fibers to thoracic and abdominal organs.

vasa deferentia The spermatic duct of the testicles; also called vas deferens.

veins The blood vessels that transport blood back to the heart.

venous sinuses Spaces between the membranes surrounding the brain that are the primary means of venous drainage from the brain.

ventilation The exchange of air between the lungs and the air of the environment, spontaneously by the patient or with assistance.

ventral respiratory group (VRG) A portion of the medulla oblongata that is responsible for modulating breathing during speech.

ventricle In the context of the circulatory system, one of two lower chambers of the heart; in the context of the neurologic system, hollow storage areas in the brain.

vertebrae The 33 bones that make up the spinal column.

vertebral column The spine or primary support structure of the body that houses the spinal cord and the peripheral nerves.

visceral pleura The pleural membrane that covers the lungs.

vital capacity The amount of air that can be forcibly expelled from the lungs after breathing in as deeply as possible.

voluntary muscle Muscle that is under direct voluntary control of the brain and can be contracted or relaxed at will; skeletal, or striated, muscle.

vulva The female external genitalia; also called the pudendum.

white blood cells (WBCs) Blood cells that have a role in the body's immune defense mechanisms; they provide immunity, fight infection, and remove dead cells; also called leukocytes.

xiphoid process The narrow, cartilaginous lower tip of the sternum.

zygoma The quadrangular bone of the cheek, articulating with the frontal bone, the maxillae, the zygomatic processes of the temporal bone, and the great wings of the sphenoid bone.

Chapter 8

Pathophysiology

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Pathophysiology

Integrates comprehensive knowledge of pathophysiology of major human systems.

KNOWLEDGE OBJECTIVES

1. Define pathophysiology, including its role in diagnosing and treating disease. (p 368)
2. Compare atrophy, hypertrophy, hyperplasia, dysplasia, and metaplasia as means of cellular adaptation. (p 368)
3. List factors that can affect or upset homeostasis. (p 369)
4. Explain the causes, clinical manifestations, assessment, and management of edema. (p 370)
5. Discuss types of fluid deficits and potential resulting complications. (p 371)
6. Explain the physiologic consequences of electrolyte imbalances in sodium, potassium, calcium, phosphate, and magnesium. (pp 371–374)
7. Compare respiratory acidosis, respiratory alkalosis, metabolic acidosis, and metabolic alkalosis. (pp 375–378)
8. Outline how cellular injury occurs in patients with hypoxia, chemical exposures, infection (sepsis), immunologic exposures (hypersensitivity reactions), inflammatory conditions, genetic disorders, nutritional imbalances, physical damage (mechanical injury), and other harmful exposures, such as extremes of hot and cold. (pp 378–382)
9. Examine the concept of apoptosis. (pp 382–383)
10. Define perfusion, including the physiologic consequences of hypoperfusion. (pp 383–384)
11. Analyze the mechanisms by which the body compensates for hypoperfusion. (pp 383–384)
12. Discuss the causes of central and peripheral shock, including cardiogenic, obstructive, hypovolemic, and distributive shock. (pp 384–386)
13. Explain how to treat a patient in shock. (p 387)
14. Describe multiple organ dysfunction syndrome. (pp 387–389)
15. Examine the body's three defense mechanisms against pathogens: anatomic barriers, the immune response, and the inflammatory response. (pp 389–400)
16. Explain how plasma protein systems—the complement system, the coagulation (clotting) system, and the kinin system—modulate the inflammatory response. (p 397)
17. Compare wound healing by primary intention with wound healing by secondary intention. (pp 398–400)
18. Outline each of the four types of hypersensitivity reactions and mechanisms for immunologic injury. (pp 401–403)
19. List several autoimmune reactions. (pp 403–404)
20. Compare inherited and acquired immunodeficiencies. (pp 404–405)

PHOTO: © Kateryna Kon/Shutterstock.

21. Analyze the controllable and uncontrollable risk factors that intersect in order to cause disease. (pp 405–406)
22. Outline how incidence, prevalence, morbidity, and mortality data are used to analyze disease risk. (p 406)
23. Analyze risk factors for cancer and cardiovascular disease. (pp 408–412)
24. Describe how hematologic disorders occur. (pp 409–410)
25. Name common renal, gastrointestinal, and neuromuscular disorders. (pp 412–415)
26. List the stages of the general adaptation syndrome, and explore the relationship between stress and disease. (pp 415–418)

SKILLS OBJECTIVES

There are no skills objectives in this chapter.

Introduction

The human body is made up of cells, tissues, and organs. These structures function in a constantly changing microenvironment. The study of the origin, growth, structure, behavior, and reproduction of living organisms is known as *biology*. **Pathophysiology** is the study of the physiology of altered functioning in the presence of disease. The word is derived from the Greek words *pathos*, meaning suffering, and *physis*, meaning form. When the structure and function in cells, tissues, and organs break down in response to stressors and the body can no longer maintain homeostasis, disease may result. Determining the origin of a disease process often helps advanced emergency medical technicians (AEMTs) choose the best approach to patient evaluation and initial treatment. Chapter 7, *The Human Body*, discusses the major classes of cells, as well as cellular structure and function.

To understand disease processes, you must understand the ways disease alters the structure and function in cells. We begin this chapter by reviewing how the changes that affect cells disrupt the body's ability to maintain homeostasis and lead to disease. Next, we consider the influence inflammation and shock have on disease development. We also discuss the role of immunity and defense mechanisms in protecting the organism from disease. We conclude with a discussion on the effects genetics and stress have in disease development.

Adaptations in Cells and Tissues

When exposed to adverse conditions, cells undergo a process of adaptation in an attempt to guard

against injury. In some situations, the cells change permanently; in others, the structure or function of the cells changes only temporarily.

Atrophy is a decrease in cell size due to a loss of subcellular components, which leads to a decrease in the size of the tissue and organ. The actual number of cells remains unchanged. The decreased size represents an attempt to cope with a new steady state in less-than-favorable conditions or a lack of use. For example, a casted, immobilized limb shrinks in muscle mass as a result of disuse atrophy.

Hypertrophy is an increase in the size of the cells due to synthesis of more subcellular components, which leads to an increase in tissue and organ size. For example, the left ventricle in the heart may undergo hypertrophy as a result of chronic high resistance pressures from hypertension (elevated blood pressure).

Hyperplasia is an increase in the actual number of cells in an organ or tissue, usually resulting in an increase in the size of the organ or tissue. For example, a callus represents hyperplasia of the keratinized layer of the epidermis of the foot in response to increased friction or trauma.

Dysplasia is an alteration of the size, shape, and organization of cells. It is most often found in epithelial cells that have undergone irregular, atypical changes in response to chronic irritation or inflammation. For example, the development of cervical dysplasia in women is strongly associated with exposure to certain human papillomaviruses.

Metaplasia refers to the reversible cellular adaptation in which one adult cell type is replaced by another adult cell type. For example, in squamous metaplasia, the ciliated epithelium in the airways of smokers may be replaced by metaplastic epithelium.

Disturbances in Fluid Balance

The human body is composed primarily of water. Therefore, all biochemical reactions taking place within the body are occurring in an aqueous environment. As a result, changes in fluid and electrolyte balance that disrupt homeostasis can either cause or exacerbate various disease processes. The result may be an emergent condition.

Homeostasis can be upset in several ways, such as excessive output or input of fluids. Profuse sweating can cause dehydration, whereas excessive salt intake can contribute to hypertension.¹ Not drinking enough water can also alter homeostasis. In fact, a person deprived of water for 3 days or longer may die.

The degree of fluid imbalance required to compromise homeostasis and cause illness depends on the patient's size, age, and any underlying medical conditions. In healthy adults, loss of more than 30% of total body fluid is required, but in a small child, a loss of only 10% to 15% of total body fluid could easily produce symptoms of dehydration. Consequently, fluid therapy is a fundamental step in resuscitation.

Words of Wisdom

A hypertonic solution has a relatively higher osmotic pressure—that is, it contains more solute—than does the interstitial fluid or the fluid within and surrounding the brain. Administering a hypertonic solution such as mannitol, sodium bicarbonate, or hypertonic saline can cause excess fluid to drain from the tissues and into the blood and can decrease swelling in the brain.

Special Populations

The total volume of water in the body varies by age and body composition throughout the life span. At birth, a healthy, full-term neonate has approximately 80% total body water; however, this percentage decreases with age (**FIGURE 8-1**). After several weeks, an infant's total body water drops to approximately 70%.² In childhood, the percentage of total body water decreases to around 60%. Adults have 50% to 60% total body water, but water may constitute only 45% of body weight in older adults. Dehydration, therefore, can be a serious concern in older adults. Dehydration also remains a concern in the pediatric population. Despite infants having higher total body water content than adults, infants are at higher risk of dehydration due to increased rate of fluid loss during disease and pathologic states.

FIGURE 8-1 Average total water volume in the body by age.

YOU are the Provider

Part 1

You and your partner are dispatched to a single-family residence to assist a 72-year-old man who is having difficulty breathing. On arrival, a neighbor greets you at the door. She tells you the resident of the home—your patient—lives alone, has had numerous heart attacks, and is not doing well. As you approach him, you assess his surroundings. You observe a large pile of used facial tissues on the side table, along with an array of prescription medication bottles. The patient is sitting upright in a chair. He is wearing a nasal cannula attached to a home oxygen unit. He is able to speak only a few words at a time. He says he cannot breathe, and you note that he looks pale.

1. What is your general impression of the patient?
2. What can you learn about the patient from his surroundings?

FIGURE 8-2 Edema is an excessive amount of fluid in the interstitial space.

© Dr P. Marazzi/Science Source.

Edema

Edema is swelling caused by excessive fluid trapped in the body tissues (**FIGURE 8-2**). Edema may have any of several causes. One possible cause is increased capillary hydrostatic pressure, which may be associated with any of the following:

- Arteriolar dilation (for example, from allergic reactions or inflammation)
- Venous obstruction (for example, hepatic obstruction, heart failure, or thrombophlebitis)
- Increased vascular volume, as occurs in patients with heart failure
- An increased level of adrenocortical hormones
- Premenstrual sodium retention
- Pregnancy
- Environmental heat stress
- The effects of gravity from prolonged standing

Decreased colloidal osmotic pressure in the capillaries, another possible cause of edema, can be associated with various processes:

- Decreased production of plasma proteins, such as occurs in starvation and in patients with liver disease or severe protein deficiency
- Increased loss of plasma proteins attributable to protein-losing kidney diseases, extensive burns, or other causes

Obstruction of lymphatic vessels also can cause edema. Such obstruction can be associated with infection, lymphatic disease, or removal of lymphatic structures (for example, removal of lymph nodes during mastectomy can cause upper extremity

edema). When lymph vessels are blocked, the amount of fluid exiting through the arterial end of the capillaries is not equal to the amount of fluid being returned to the venous side. Consequently, more fluid leaves the arterial side, where the mean forces favoring outward movement are slightly higher. This additional fluid is picked up by the lymphatic system.

Severe edema, then, may be caused by long-standing lymphatic obstruction. Peripheral edema (as in the ankles and feet) is the most common form. If a person is unable to get out of bed for an extended period, then edema may occur in the sacral area (sacral edema). *Ascites*, the abnormal accumulation of fluid in the peritoneal cavity, is also a type of edema.

The clinical manifestations of edema may be local or generalized. Patients with cardiac disease may have pulmonary edema, or edema may occur due to blast injuries, narcotic overdose, or altitude changes (ie, high altitude pulmonary edema). Patients with acute pulmonary edema have an excessive amount of fluid in their lungs, which impairs the diffusion of oxygen into pulmonary capillaries, making the patient hypoxic and severely short of breath.

AEMTs must perform an in-depth physical assessment that includes auscultation of breath sounds, evaluation for pedal and sacral edema and jugular venous distention, and vital signs. Along with a thorough exam, it is important to obtain a patient's medical history, including current and past medications. Often, treatment is determined by the patient's chief complaint and presenting problem. The definitive treatment of edema depends on the underlying medical condition that caused it. Possible interventions may include the use of continuous positive airway pressure, supplemental oxygen, positional therapy, nitrates, and diuretics.

Words of Wisdom

When you eat a bag of potato chips, you ingest a large quantity of salt. Acutely, the body responds by holding on to water. Hence, urine output temporarily declines. In healthy people, however, the kidneys and other regulatory mechanisms return both sodium and water levels to normal homeostatic balance.

TABLE 8-1 Isotonic Fluid Deficit/Excess (Hypovolemia/Hypervolemia)

Imbalance	Common Causes
Fluid deficit (proportionate loss in both water and sodium; decreased total body sodium)	Vomiting, diarrhea, loss of plasma or whole blood (eg, burns, hemorrhage), loop diuretic use, excessive sweating, fever, decreased oral fluid intake
Fluid excess (Proportionate gain in both water and sodium; increased total body sodium)	Heart failure, cirrhosis, renal failure, steroid use, excessive sodium intake

Data from: Monahan FD. *Phipps' Medical-Surgical Nursing: Health and Illness Perspectives*. 8th ed. St. Louis, MO: Mosby; 2007:359; and Potter P, Perry A, Stockert P, Hall A. *Basic Nursing*. 7th ed. St. Louis, MO: Mosby; 2011:466.

Isotonic Fluid Deficit

An isotonic fluid deficit is a decrease in extracellular fluid with proportionate losses of sodium and water (**TABLE 8-1**). This is the most common form of fluid loss, and is often the result of sweating. Excessive sweating or combining increased physical exertion with other comorbidities may complicate the fluid loss and cause additional problems. An isotonic fluid excess is a proportionate increase of sodium and water in extracellular fluid; common causes include kidney and heart failure. The manifestations of these conditions depend on the serum sodium level. When the body becomes dehydrated, orthostatic hypotension and decreased urine output (**oliguria**) often occur. When the sodium level is excessively high (greater than 160 mEq/L), the patient is at risk of delirium and coma. Tonicity and related concepts are covered in detail in Chapter 13, *Vascular Access and Medication Administration*.

Electrolyte Imbalances

Sodium

Sodium, an element essential to the human body, is found primarily in the blood and fluid outside the cells. It regulates fluid balance, total fluid volume, and blood pressure by controlling the movement of water across cellular membranes. It also facilitates muscle contraction and nerve impulse transmission. Abnormal sodium levels may result in nausea,

seizures, and cardiac dysrhythmias. A blood test can determine the level of serum sodium (Na^+); the normal range is 135 to 145 mEq/L.³ A *hypertonic fluid deficit* occurs when there is water loss in the body without a proportionate loss of sodium—in other words, there is a relative water loss. This condition, called **hypernatremia**, is clinically defined as a serum sodium level of 146 mEq/L or higher. A hypotonic fluid deficit occurs when there is sodium loss in the body without a proportionate loss of water (there is a relative water excess). This deficit causes **hyponatremia**, characterized by a serum sodium level of 134 mEq/L or less.

Causes of hypernatremia and hyponatremia include excessive sweating in the heat or during exercise, gastrointestinal losses through vomiting or diarrhea, and inappropriate use of intravenous (IV) fluids or diuretics. Some patients have nausea and headaches. In others, seizures and coma develop. Clinical findings typically depend not only on the absolute sodium level, but also on when the abnormality developed. People who become hyponatremic over a period of days tend to have fewer symptoms than people in whom the abnormality develops acutely.

Potassium

Potassium (K^+), the major intracellular cation, is crucial to many cellular functions, including neuromuscular control; regulating skeletal, smooth, and cardiac muscles; regulating acid-base balance; facilitating intracellular enzyme reactions; and maintaining intracellular osmolarity. The normal serum level of potassium ranges from 3.5 to 5.0 mEq/L.³

Hypokalemia is a decreased serum potassium level. Common causes include the following:

- Decreased dietary potassium intake and absorption
- Decreased shift of potassium into the cells as a result of insulin administration, alkalosis, or beta adrenergic stimulation, such as with epinephrine
- Renal potassium loss, such as with increased aldosterone activity or diuretic use
- Extrarenal potassium loss, such as with vomiting, diarrhea, or laxative use

Muscular weakness, fatigue, and muscle cramps are the most frequent symptoms associated with mild to moderate hypokalemia.

Hyperkalemia is an elevated serum potassium level. Here are some common causes you may see in the prehospital setting:

- Decreased excretion (from renal failure or from medications that inhibit potassium excretion [spironolactone, angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory drugs])
- Shifts of potassium from within the cell (as with burns, crush injuries, metabolic acidosis, and insulin deficiency)
- Excessive dietary potassium intake

An elevated potassium level interferes with normal neuromuscular function, resulting in muscle weakness and, rarely, flaccid paralysis.

Calcium

Nearly all (98%) of the body's calcium (Ca^{+2}) is found in the bones and teeth. This element lends strength and stability to the collagen and ground substance that form the matrix of the skeletal system. Calcium enters the body through the gastrointestinal tract. Its absorption from the intestine is aided by vitamin D (**FIGURE 8-3**), which is manufactured largely

FIGURE 8-3 Regulation of the blood calcium level. Calcitonin is a fast-acting hormone, but has only a weak effect because any decrease in Ca^{2+} ion concentration triggers the release of parathyroid hormone (PTH). PTH almost completely overrides the calcitonin effect. In a patient with a prolonged calcium elevation or deficiency, the action of PTH is the most powerful hormonal mechanism for maintaining a normal blood calcium level.

by the body in a complex process that begins with exposure of the skin to sunlight. Calcium is then stored in bone tissue and ultimately excreted by the kidney. A normal serum calcium level ranges from 8.6 to 10.2 mg/dL.³

Hypocalcemia, a decreased serum calcium level, can be caused by the following:

- Decreased calcium intake or absorption (as in malabsorption and vitamin D deficit)
- Increased calcium loss (as in alcoholism and diuretic therapy)
- Endocrine disease (such as hypoparathyroidism)
- Sepsis

Signs and symptoms of hypocalcemia stem from the increased excitation of the neuromuscular and cardiovascular systems. Skeletal muscle spasm can cause cramps or sustained muscle contraction (tetany). Laryngospasm with stridor can obstruct the airway. Seizures can occur, as can abnormal sensations (paresthesias) affecting the lips and extremities.

Hypercalcemia is an increased serum calcium level. Selected causes are listed below:

- Increased calcium intake or absorption (such as with excessive antacid ingestion)
- Endocrine disorders (such as primary hyperparathyroidism and adrenal insufficiency)
- Neoplasms (cancers)
- Miscellaneous causes (such as diuretics and sarcoidosis)

The signs and symptoms associated with hypercalcemia are sometimes vague and can include fatigue, weakness, nausea, constipation, and frequent urination (**polyuria**). In severe cases, stupor, coma, or renal failure may develop. Treatment of hypercalcemia depends on treating the underlying cause.

Phosphate

Phosphate (PO_4^{3-}), primarily an intracellular anion, is essential to many body functions.

Hypophosphatemia is a decrease in the level of serum phosphate. Causes include the following:

- Decreased supply or absorption, as can occur in starvation, malabsorption, or blocked absorption (such as with aluminum-containing antacids)
- Excessive loss of phosphate associated with use of diuretics, or in patients with hyperparathyroidism, hyperthyroidism, or alcoholism

- Intracellular shift of phosphorus (for example, after administering glucose, anabolic steroids, or oral contraceptives, or in patients with respiratory alkalosis or salicylate poisoning)
- Electrolyte abnormalities, such as hypercalcemia and hypomagnesemia
- Abnormal loss of nutrients followed by inadequate replenishment, as can occur in patients with diabetic ketoacidosis or chronic alcoholism

Signs and symptoms can include dysrhythmias, hypotension, muscle weakness, and altered mental status. Acute, severe hypophosphatemia can lead to seizures, acute blood disorders, and increased susceptibility to infection. The breakdown of muscle fibers (rhabdomyolysis) may also occur. Treatment involves oral replenishment in mild to moderate cases. Severe cases and symptomatic patients require in-hospital IV phosphate replacement.

Hyperphosphatemia, an increased serum phosphate level, has many possible causes:

- Massive loading of phosphate into the extracellular fluid
 - Excessive use of vitamin D, laxatives, or enemas containing phosphate
 - IV phosphate supplements
 - Chemotherapy
 - Metabolic acidosis
- Decreased excretion into the urine (such as in renal failure and hypoparathyroidism, and with excessive administration of growth hormone [which results in acromegaly])

Signs and symptoms vary widely but may include tremor, paresthesia, hyperreflexia (overactive reflexes), confusion, seizures, muscle weakness, decreased mental status, coma, hypotension, or heart failure.⁴⁻⁶ The normal range for serum phosphate is 2.5 to 4.5 mg/dL.³

Magnesium

Magnesium (Mg^{+2}) is the second most abundant intracellular cation, after potassium. Approximately 50% of the body's magnesium is stored in the bones, 49% in other body cells, and the remaining 1% in the extracellular fluid. The normal range of serum magnesium is 1.6 to 2.6 mEq/L.³

TABLE 8-2 Major Electrolytes

Electrolyte	Symbol	Normal Serum Level
Sodium	Na ⁺	135–145 mEq/L
Chloride	Cl ⁻	98–107 mEq/L
Potassium	K ⁺	3.5–5.0 mEq/L
Calcium	Ca ⁺²	8.6–10.2 mg/dL
Phosphate	PO ₄ ⁻³	2.5–4.5 mg/dL
Magnesium	Mg ⁺²	1.6–2.6 mEq/L

Data from: *AMA Manual of Style*, 10th ed. Table 2: Selected Laboratory Tests, With Reference Ranges and Conversion Factors.

Hypomagnesemia, a decreased serum magnesium level, has several possible causes:

- Diminished magnesium absorption or intake (as occurs in malabsorption, chronic diarrhea, laxative abuse, or malnutrition)
- Increased renal loss of magnesium (related to diuretics, hyperaldosteronism, hypercalcemia, or volume expansion)
- Miscellaneous causes, such as diabetes, respiratory alkalosis, and pregnancy

Weakness and muscle cramps are common symptoms. A person with hypomagnesemia may have marked neuromuscular and central nervous system (CNS) hyperirritability, with tremors and jerking. Hypertension, tachycardia, or ventricular dysrhythmias may occur, and confusion and disorientation can be pronounced.

Hypermagnesemia is an increased serum magnesium level. It almost always occurs as a result of kidney insufficiency, in which the body is unable to excrete magnesium taken in from food or drugs, especially antacids and laxatives. Symptoms include muscle weakness, decreased deep tendon reflexes, and altered mental status. Weakness is common, and respiratory muscle paralysis and cardiac arrest are possible.

TABLE 8-2 summarizes the major electrolytes of the body.

Disturbances of Acid-Base Balance

Recall that pH represents the concentration of hydrogen ions (H⁺) in a solution. In other words, it is

a measure of the acidity or alkalinity of a solution. There is an inverse relationship between pH and H⁺ ion concentration: the lower the pH, the higher the acidity. See Chapter 7, *The Human Body*, for a more in-depth discussion of pH.

In the human body, maintaining pH within a narrow range is vital. Acids and bases neutralize each other; therefore, they must remain in balance for the body to preserve homeostasis. Every patient complaint you encounter as an AEMT will have a component of acid-base balance and imbalance. For example, a patient who is hyperventilating may have a resulting alkalosis (pH >7.45), whereas a patient in diabetic ketoacidosis will experience an underlying acidosis (pH <7.35).

Acidosis is an increase in extracellular H⁺ ions; **alkalosis** is a decrease in extracellular H⁺ ions.

↓ pH means ↑ H⁺ concentration = Acidosis

↑ pH means ↓ H⁺ concentration = Alkalosis

If extracellular pH is low, then the excessive concentration of H⁺ ions in the extracellular fluid (the fluid outside the cell) will signal the cell to accept more H⁺ ions, giving it an overall positive charge. To return its charge to neutral, the cell begins to shift potassium and other cations (positively charged ions) into the interstitial fluid.

Disturbances of acid-base balance are associated with disturbances of potassium balance, in part because of the kidney transport system that moves H⁺ and K⁺ in opposite directions. In acidosis, the kidneys excrete H⁺ and resorb K⁺. Conversely, in alkalosis, the kidneys resorb H⁺ and excrete K⁺. A potassium imbalance usually manifests itself as a disturbance in excitable tissues, especially those of the heart.

In addition, Ca⁺² ions shift out of the cell in response to an influx of hydrogen. Because calcium acts at the neuromuscular junction, a high serum calcium level (hypercalcemia) decreases the rate of neural transmission—the speed at which an impulse is conveyed by a neuron. A low serum calcium level (hypocalcemia), on the other hand, is characterized by hypersensitive neurons and an accelerated rate of neural transmission.

Types of Acid-Base Imbalance

Acid-base disorders are associated with four main clinical presentations: respiratory acidosis,

respiratory alkalosis, metabolic acidosis, and metabolic alkalosis. Fluctuations in the level of bicarbonate in the body cause metabolic acidosis or alkalosis, whereas respiratory disorders cause respiratory acidosis or alkalosis. When the body's buffering systems cannot immediately correct an acid-base imbalance, compensatory mechanisms respond to help restore the normal balance. For example, respiratory alkalosis may occur as a compensatory response to metabolic acidosis. Thus, patient management often involves treating more than one acid-base imbalance. Compensatory mechanisms are described in Chapter 7, *The Human Body*.

Respiratory Acidosis

The following equation demonstrates how a diminished rate of respiration can precipitate acidosis:

Respiratory acidosis is always related to hypoventilation. Decreased lung tidal volume reduces the amount of carbon dioxide (CO_2) that is exhaled, causing hypercapnia (increased CO_2). Because the acidosis is linked to inadequate breathing, the renal buffer system is initiated as a compensatory mechanism. Some causes of respiratory acidosis include the following:

- Airway obstruction
- Cardiac arrest
- Overdose of a CNS depressant drug, such as heroin
- Submersion
- Respiratory arrest
- Pulmonary edema
- Closed head injury
- Chest trauma

Hypoventilation associated with any of these conditions can devolve quickly into an overwhelming, life-threatening acidosis, making it impossible for the renal system to adequately compensate. The decrease in pH increases permeability of cell membranes, causing a leakage of potassium into the blood. The release of potassium ions into the extracellular fluid can cause a potentially fatal cardiac dysrhythmia. The discharge of calcium into extracellular spaces causes hypercalcemia, characterized by lethargy, a diminished level of consciousness, and a generalized slowing of the nervous system. This nervous system inhibition may also

be evidenced by a delayed pupillary response or a weakened or delayed response to painful stimuli.

Signs and symptoms of respiratory acidosis include the following:

- Systemic or cerebral vasodilation (or both)
- Headache, light-headedness
- Warm, flushed skin⁷
- CNS depression
- **Bradypnea** (slow respiratory rate)
- Nausea and vomiting

Chronic obstructive pulmonary disease (COPD) gradually destroys lung tissue and inhibits oxygen and carbon dioxide exchange, eventually resulting in respiratory acidosis (**FIGURE 8-4**). In some patients with COPD, the normal stimulus for gas exchange is absent. Carbon dioxide retention leads to an increasing level of carbonic acid. Chemoreceptors eventually become unable to detect the presence of metabolic acids. As a result, the only remaining breathing stimulus is the hypoxic drive, which stimulates breathing by sensing a decreased oxygen level in the blood.

The slow onset of this form of respiratory acidosis in patients with COPD makes it survivable. The renal system slowly moderates the acidosis, preventing the life-threatening cardiac dysrhythmias often associated with acute acidosis.

Words of Wisdom

Compensatory mechanisms for pH imbalances bring the pH level closer to normal. Respiratory compensation (acidosis or alkalosis) occurs rapidly and relatively predictably. Metabolic compensation, if it occurs at all, takes hours or days. Acute compensation is never complete. Chronic compensation, such as that which occurs in patients with COPD, often returns the pH level to normal.

Respiratory Alkalosis

The following equation demonstrates how an increased respiratory rate can produce alkalosis:

Respiratory alkalosis is associated with conditions that result in hyperventilation. Over time, an increased respiratory rate decreases the amount of circulating carbon dioxide in the body. In

FIGURE 8-4 **A.** Derangement of acid-base balance in respiratory acidosis. **B.** Compensation by formation of additional bicarbonate.

© Jones & Bartlett Learning.

respiratory alkalosis, the carbon dioxide level in the blood drops, which reduces the level of circulating carbonic acid (H_2CO_3). The renal system then begins to retain H^+ ions to rebalance the depleted acid level. As the same time, H^+ ions begin to shift from the intracellular fluid compartment to the extracellular fluid. Calcium moves into the intracellular fluid to rebalance the depleted hydrogen level. The resulting extracellular hypocalcemia causes muscle contractions. In fact, hyperventilation accompanied by **carpopedal spasm** (a contorted position in

which the fingers or toes flex in a clawlike manner) is the classic sign of respiratory alkalosis.

Some causes of hyperventilation and respiratory alkalosis include the following:

- Drug overdose, especially an overdose of aspirin
- Fever
- Overzealous bag-mask ventilation

Some signs and symptoms of respiratory alkalosis include the following:

- Diminished level of consciousness
- Light-headedness
- Carpopedal spasm
- Paresthesias of the lips and face
- Chest tightness
- Confusion
- Vertigo
- Blurred vision
- Nausea and vomiting

Metabolic Acidosis

The following equation demonstrates how an increased carbonic acid level can produce **metabolic acidosis**:

Carbonic acid is broken down into hydrogen and bicarbonate (HCO_3^-). The increased carbonic acid equates to increasing hydrogen, which equates to acidosis.

Any acidosis unrelated to the respiratory system is considered metabolic. An increased rate of breathing (tachypnea) represents the body's attempt to restore acid-base balance, by eliminating excess carbon dioxide through the respiratory system. For example, patients with diabetic ketoacidosis often experience Kussmaul respirations (deep, closely spaced, sighing breaths), in which the body hyperventilates in an attempt to blow off carbon dioxide and correct the acidosis.

As with any acidosis, the extracellular hydrogen ion level increases and extracellular buffers attempt to neutralize the excess acid. Ion shifts occur, hydrogen ions leak into the cells, and potassium shifts into the extracellular spaces, raising the serum potassium level and putting the patient at risk of a life-threatening dysrhythmia. Calcium also shifts into the extracellular spaces. The resulting

hypercalcemia obstructs impulse transmission to neurons in muscle and other tissues. Consequently, the patient becomes lethargic and has a decreased level of consciousness.

Causes of metabolic acidosis include the following:

- **Lactic acidosis.** **Lactic acidosis** is the product of anaerobic cellular respiration, which occurs when tissues and organs are inadequately perfused, as in shock and cardiac arrest.
- **Ketoacidosis.** **Ketoacidosis** is associated with insulin deficiency or desensitization of cells to insulin. Unable to use glucose for energy, cells must instead begin metabolizing fatty acids. Extremely acidic compounds called **ketones** are the by-products of such metabolism.
- **Aspirin (acetylsalicylic acid) overdose.** An aspirin dose of 150 mg/kg or above in an adult constitutes an overdose. Aspirin directly stimulates the respiratory centers of the brain, producing tachypnea. Rapid breathing leads to respiratory alkalosis, and initiation of renal compensatory mechanisms leads to metabolic acidosis.
- **Alcohol ingestion.** Ingesting an excessive amount of ethyl alcohol can induce **alcoholic ketoacidosis**. Ingesting as little as 30 mL of either methanol (wood alcohol) or ethylene glycol (antifreeze) can also induce fatal forms of acidosis.

- **Gastrointestinal losses.** Gastrointestinal losses can precipitate metabolic acidosis. Diarrhea, for example, removes bases from the lower intestinal tract.
- **Carbon monoxide poisoning.**

The clinical presentation of metabolic acidosis is similar to that of respiratory acidosis:^{7,8}

- Vasodilation
- CNS depression
- Headaches
- Warm, flushed skin
- Tachypnea
- Nausea and vomiting
- Cardiac dysrhythmias

Metabolic Alkalosis

The following equation demonstrates how a decreased H^+ ion concentration can produce alkalosis:

Metabolic alkalosis occurs when increased urine output or a decreased gastric acid level leads to an excessive loss of acid. This is rarely an acute condition, but it is common among chronically ill patients, especially those who require nasogastric suctioning.

Several factors associated with upper gastrointestinal losses can lead to metabolic alkalosis:

- **Excessive vomiting.** Illness or an eating disorder, such as anorexia nervosa or bulimia,

YOU are the Provider

Part 2

You ask your partner to obtain a baseline oxygen saturation level and obtain measurements for baseline vital signs, and to include waveform capnography. While she is setting up her equipment, you ask the patient about his past medical history. With great difficulty, he replies, "Heart failure."

Recording Time: 1 Minute

Appearance	Awake, in distress, anxious
Level of consciousness	Alert (oriented to person, place, and time)
Airway	Open
Breathing	Accelerated rate; accessory muscle use; productive cough
Circulation	Weak radial pulses; moist, pale, cool skin

3. How does the recruitment of accessory muscles facilitate breathing?
4. How might the productive cough help you identify the source of the patient's breathing difficulty?

can be responsible for upper gastrointestinal acid loss. Expelling a great deal of acid from the stomach can trigger a complex metabolic pathway that leads to metabolic alkalosis.

- **Excessive water intake.** Drinking large amounts of water during vigorous exercise not only dilutes the stomach acid, but also stimulates the small intestine to prepare for incoming food from the stomach. An outpouring of strongly alkaline digestive enzymes into the lower gastrointestinal tract exacerbates any existing acid-base imbalance.
- **Nasogastric suctioning.** Removal of contents directly from the gastrointestinal tract eliminates acids from the body, resulting in alkalosis.
- **Excessive intake of alkaline substances.** Metabolic alkalosis can stem from excessive reliance on antacids or similar alkaline substances. This possibility is important to remember when assessing a patient with cardiac disease who reports having self-medicated for hours or days with over-the-counter antacids.

The respiratory system serves as the compensatory mechanism for metabolic alkalosis. Bradypnea develops to correct the diminished H^+ ion level by retaining carbon dioxide, thereby driving up levels of circulating acids.

Signs and symptoms of metabolic alkalosis include the following:

- Confusion
- Muscle tremors and cramps
- Bradypnea
- Hypotension

Cellular Injury

The manifestations of cellular injury or death depend on how many and which types of cells are damaged. Various processes may cause cellular injury:

- Hypoxia (lack of oxygen)
- Ischemia (lack of blood supply)
- Chemical injury
- Infectious injury
- Immunologic (hypersensitivity) injury
- Physical damage (mechanical injury)
- Inflammatory injury

Manifestations of cellular injury occur at the microscopic (structural) and functional levels.

Common microscopic abnormalities (such as cardiac cell **necrosis** [a process in which the cell breaks down] as a result of long-standing hypoxemia) include cell swelling, rupture of cell membranes or nuclear membranes, and breakdown of nuclear material such as chromosomes (**FIGURE 8-5**). This kind

A

B

FIGURE 8-5 Comparison of cardiac muscle fibers (**A**) with necrotic fibers (**B**). Note fragmentation of fibers, loss of nuclear staining, and fragmented bits of nuclear debris. Cellular injury causes swelling, resulting in nuclear membrane rupture and breakdown of the nuclear material (magnification $\times 400$).

of damage often distorts the shape of a cell and disrupts its function. Functional disturbances may include inefficient oxygen utilization, intracellular acidosis, toxic waste accumulation, and derangement of nutrient metabolism.

Changes in individual cells often affect the entire organism. In some cases, the changes are associated with only minor systemic abnormalities, such as fever. At other times, such as when renal failure occurs, entire organ systems collapse and the patient's condition becomes critical. Because all body systems are connected, dysfunction in one system inevitably affects the function of other systems, upsetting the homeostatic balance on which the body depends to sustain life.

With proper treatment, cellular injury can be repaired, up to a point; however, when irreversible injury occurs, treatment is futile. Cell death is followed by necrosis. The cell membrane becomes abnormally permeable, allowing an influx of electrolytes and fluids. Then the cell and its organelles swell, and lysosomes release enzymes that destroy intracellular components. These processes occur during and after cell death.

Hypoxic Injury

Hypoxic injury is a common—and often deadly—cause of cellular injury. It may result from decreased amounts of oxygen in the air or loss of hemoglobin function (such as in carbon monoxide poisoning), a decreased number of red blood cells (as from bleeding), disease of the respiratory or cardiovascular system (such as COPD), or loss of cytochromes (mitochondrial proteins that convert oxygen to adenosine triphosphate [ATP], like that seen in cyanide poisoning).

Although hypoxia has deleterious effects on cells, the damage does not stop there. Cells that are hypoxic for more than a few seconds produce mediators (substances) that may damage areas near or far from the initial area of damage in the body. The result is a positive feedback cycle in which mediators lead to more cell damage, which leads to more hypoxia, which leads to further mediator production, and so forth.

The earliest and most dangerous mediators produced by cells in response to hypoxia are **free radicals**. A free radical molecule is missing one electron in its outer shell. The presence of an odd,

unpaired electron causes chemical instability as free radicals randomly attack cells and membranes in an attempt to steal back the missing electron. The result is widespread and potentially deadly tissue damage.

Chemical Injury

A variety of chemicals, including poisons, lead, carbon monoxide, ethanol, and pharmacologic agents, may injure and ultimately destroy cells. Common poisons include cyanide and pesticides. Cyanide induces cell hypoxia by blocking oxidative phosphorylation in the mitochondria and preventing the metabolism of oxygen. Pesticides block an enzyme, acetylcholinesterase, thereby preventing proper transmission of nerve impulses.

Long-term ingestion of lead, such as that caused by chewing on windowsills painted with lead-based paint, leads to brain injury and neurologic dysfunction. The ability of lead to substitute for calcium (molecules of lead and calcium are a similar size) is a common factor in many of its toxic actions. Most likely, lead occupies the space normally held for calcium in vital biochemical reactions, leading to abnormal results and dysfunction.

Carbon monoxide binds to hemoglobin more easily than does oxygen, preventing adequate oxygenation of the tissues. A low-level exposure of carbon monoxide causes nausea, vomiting, and headache. A higher level can be rapidly fatal.⁹

At lower doses, ethanol, as found in drinking alcohol, causes the well-known effects of inebriation. Higher doses produce severe CNS depression and hypoventilation, sometimes precipitating cardiovascular collapse.

Some pharmacologic agents produce toxic substances when the agents are metabolized in the body, especially in overdose conditions. For example, acute overdose occurs when an excessive dose of acetaminophen (Tylenol) is ingested. If an adult takes more than 7.5 g in a single dose, the toxins that accumulate can poison the liver and can be fatal.

Infectious Injury

Infectious injury to cells occurs as a result of an invasion of bacteria, fungi, or viruses. Bacteria may cause injury by direct action on cells or by the production of toxins. Viruses often initiate an

inflammatory response that leads to cell damage and patient symptoms.

Virulence measures the disease-causing ability of a microorganism. The pathogenicity of any particular microorganism is a function of its ability to reproduce and cause disease within the human body. In particular, the growth and survival of bacteria in the body depend on the effectiveness of the body's own defense mechanisms and on the bacteria's ability to resist the mechanisms. A depressed immune system is less capable of fighting off microorganisms that the body perceives as harmful; populations with weaker immune systems include newborn infants, older adults, people with diabetes, and people with cancer or other chronic diseases.

Bacteria

Many bacteria have a capsule that protects them from ingestion and destruction by **phagocytes**—cells (that is, white blood cells) that engulf and consume foreign material such as microorganisms and cellular debris (**FIGURE 8-6**). However, not all bacteria are encapsulated. *Mycobacterium tuberculosis*, for example, lacks a capsule, yet stubbornly resists destruction; it can be transported by phagocytes throughout the body.

When cells are injured, circulating white blood cells are attracted to the site of injury. White blood cells release endogenous **pyrogens**, which then cause a fever to develop. Indeed, the body's most common reaction to the presence of bacteria is inflammation. Some bacteria have the capability to produce hypersensitivity reactions. The presence of bacteria in the blood is called bacteremia; septicemia (sepsis) is a systemic disease, which may be life threatening, and is caused by the proliferation of microorganisms (or related toxins) in the blood.

Viruses

Viruses are among the most common causes of afflictions. Viruses are intracellular parasites that take over the metabolic processes of the host cell and use the cell to help them replicate. A virus consists of a nucleic acid core of ribonucleic acid (RNA) or deoxyribonucleic acid (DNA). Surrounding the viral core is a protein coat known as the capsid, which protects the virus from phagocytosis. Some viruses have an additional protective coat known as the envelope.

FIGURE 8-6 General structure of a bacterium. **A.** Bacteria come in many shapes and sizes, but all have a circular strand of deoxyribonucleic acid (DNA), cytoplasm, and a plasma membrane. A cell wall surrounds the membrane in many bacteria. **B.** An electron micrograph of *Salmonella* bacteria. Many bacteria have a capsule that protects them from ingestion and destruction by phagocytes.

A: © Jones & Bartlett Learning; **B:** Courtesy of Rocky Mountain Laboratory, NIAID, NIH.

The replication of a virus occurs inside the host cell because viruses do not have their own organelles. Viral infection of a host cell leads to a decreased synthesis of macromolecules that are vital to the host cell. Viruses induce pathology by disrupting the normal metabolic processes, but are protected from antibiotics by living and replicating inside the host cell and effectively hiding from medications.

A symbiotic relationship may exist between a virus and normal cells that allows the virus to persist without causing an active infection. Viruses such as

the human immunodeficiency virus (HIV) can elicit a strong immune response, rapidly producing an irreversible, lethal injury in susceptible cells.

Immunologic and Inflammatory Injury

Inflammation is a protective response occurring in the presence of cellular injury, including trauma, infection, and hypoxia. Infection is characterized by an invasion of microorganisms that causes cell or tissue injury, which leads to the **inflammatory response**. The inflammatory response can be triggered by an agent that is physical (heat or cold), chemical (such as concentrated acid or alkali or another caustic chemical), or microbiologic (such as a bacterium or virus). The inflammatory response is characterized by both local and systemic effects, as shown in **FIGURE 8-7** and discussed in detail later in this chapter.

Local effects consist of dilation (expansion) of blood vessels and increased vascular permeability. Leukocytes (white blood cells) are attracted to the site of injury. The leukocytes adhere to the endothelium of the small blood vessels, exert force to break

through the cell walls, and migrate to the area of tissue damage. The characteristic signs of inflammation are heat, redness, tenderness, swelling, and pain. The increased warmth and redness of the inflamed tissues are caused by the dilation of capillaries and the slowing of blood flow through the vessels. Swelling occurs because the extravasation (leakage) of plasma from the dilated and more permeable vessels causes the volume of fluid in the inflamed tissue to increase. The tenderness and pain are secondary to irritation of sensory nerve endings at the site of the inflammatory process.

If the inflammatory process is severe, then systemic effects become evident. The person feels ill, and the body temperature is elevated. The bone marrow accelerates its production of leukocytes so the number of leukocytes circulating in the bloodstream increases; this increase in the number of leukocytes in the blood is called **leukocytosis**. The liver produces several proteins called acute phase proteins that are released into the bloodstream in response to tissue injury or inflammation, which help protect the body from the tissue injury caused by the inflammation. The best known of these proteins is called C-reactive protein, which is often

FIGURE 8-7 Local and systemic effects of tissue injury caused by various agents.

measured to monitor the activity of diseases characterized by tissue inflammation.

The outcome of an inflammation response depends on the amount of tissue damage. If the inflammation is mild, then it soon subsides, and the tissues return to normal. If the inflammatory process is more severe, then tissue is destroyed to some extent and must be repaired. During healing, damaged cells are replaced, and the framework of the injured tissue is repaired as an ingrowth of cells produces connective tissue fibers and new blood vessels. Scar tissue replaces large areas of tissue destruction. Sometimes, the scarring subsequent to a severe inflammation is so severe that function is seriously disturbed.

Cellular membranes may be injured when they come in direct contact with the cellular and chemical components of the immune or inflammatory process, such as phagocytes (neutrophils and macrophages), histamine, antibodies, and lymphokines. In such a case, potassium leaks out of the damaged cell and water flows inward, causing the cell to swell. The nuclear envelope, organelle membranes, and cell membrane may rupture, leading to cell death. The degree of swelling and chance of membrane rupture depend on the severity of the immune and inflammatory responses.

Injurious Genetic Factors

Genetic factors that may damage cells include chromosomal disorders, premature development of atherosclerosis, and, sometimes, obesity. An abnormal gene may develop in a person in one of three ways: by mutation of the gene during meiosis, which affects the newly formed fetus; by heredity; or as a result of other causes later in life. In trisomy 21 (Down syndrome), the child is born with an extra chromosome 21. Rheumatoid arthritis is another example of a disease with a genetic link.

Injurious Nutritional Imbalances

Good nutrition is required to maintain good health and assist the cells in fighting disease. Injurious nutritional imbalances that can injure cells and the organism as a whole include obesity, malnutrition, vitamin excess or deficiency, and mineral excess or deficiency. These conditions can lead to alterations in physical growth, mental and intellectual retardation, and even death.

Injurious Physical Agents or Conditions

Physical agents, such as heat, cold, and radiation, may also cause cell injury—for example, burns, frostbite, radiation sickness, and tumors. The degree of cell injury that results is determined by the strength of the agent and the length of exposure.

Apoptosis

Apoptosis is normal cell death. It is unique in that it is genetically programmed into the cell as a part of normal development, organogenesis, immune function, and tissue growth. It has a normal role in aging, early development, menses, lactating breast tissue, thymus involution, and red blood cell turnover.

During apoptosis, cells exhibit characteristic nuclear changes, and they typically die in well-defined clusters rather than in a random manner. The molecular mechanism underlying apoptosis involves the activation of genes that encode for proteins known as caspases (*cysteine-aspartic proteases*). The production of these proteins essentially leads to cell suicide. Unlike in the case of cell death from disease processes, proteins and DNA undergo controlled degradation that allows their remnants to be taken up and reused by neighboring cells. In this way, apoptosis allows the body to eliminate a cell but recycle many of its components. Pathologically, areas that have undergone apoptotic death do not show any evidence of inflammation. In contrast, an inflammatory response is typically observed when cells undergo necrosis from hypoxia or cellular toxins.

Apoptosis can be activated prematurely by pathologic factors such as cell injury. This sort of premature stimulation, which occurs in some forms of heart failure, causes early cell death. Another example of pathologic apoptosis is the death of hepatocytes (liver cells) in patients with viral hepatitis. The dying cells form lumps of chromatin known as Councilman bodies. Inhibition of the normal course of apoptosis allows destructive cellular proliferation, such as in cancer and rheumatoid arthritis (uncontrolled synovial tissue proliferation). **FIGURE 8-8** illustrates the process by which cancerous cells develop from normal cells.

Abnormal Cell Death

If the injury leading to cellular degeneration is of sufficient intensity and duration, then irreversible

FIGURE 8-8 The onset of cancer. Viruses and other factors induce a normal cell to become abnormal. When the immune system is working effectively, it destroys the abnormal cells, so no cancer develops. When abnormal cells evade the immune system, they form a tumor and may become a spreading cancer.

© Jones & Bartlett Learning.

cell injury leads to cell death. *Necrosis* is the term for tissue death. Necrosis is the result of the morphologic changes that occur following cell death in living tissues.

Hypoperfusion

Perfusion is defined as the delivery of oxygen and nutrients and removal of wastes from the cells, organs, and tissues by the circulatory system. Adequate circulation depends on a pumping heart, intact vascular system, and an appropriate amount of oxygen-carrying blood. A deficiency in any of these areas will cause problems with perfusion. **Hypoperfusion** occurs when the level of tissue perfusion decreases below normal. It is important to evaluate a patient's level of organ perfusion during emergency medical care, especially in diagnosing shock.

When the body senses tissue hypoperfusion, it sets compensatory mechanisms into motion. In some cases, this action is sufficient to stabilize the patient's condition. At this point, the shock is called compensated shock. In other cases, the hypoperfusion overwhelms the normal compensatory mechanisms and the patient's condition progressively

TABLE 8-3 Signs and Symptoms of Compensated and Decompensated Hypoperfusion (Shock)

Compensated	Decompensated
Agitation, anxiety, restlessness	Altered mental status (verbal to unresponsive)
Sense of impending doom	Dilated pupils
Weak, rapid (thready) pulse	Thready or absent peripheral pulses
Clammy (cool, moist) skin	Ashen, mottled, or cyanotic skin
Pallor with cyanotic lips	
Shortness of breath	Labored or irregular breathing
Nausea, vomiting	Diminished urine output (oliguria)
Delayed capillary refill time in infants and children	Impending cardiac arrest
Thirst	
Normal blood pressure	Hypotension

© Jones & Bartlett Learning.

deteriorates; this is called decompensated (hypotensive) shock (**TABLE 8-3**).

In response to hypoperfusion, the body releases catecholamines (epinephrine and norepinephrine), which produce increased strength of cardiac contraction (positive inotropy), increased pulse rate, vasoconstriction, and, consequently, increased systemic vascular resistance. In addition, the renin-angiotensin-aldosterone system is activated and antidiuretic hormone is released from the pituitary gland. Together, these actions trigger salt and water retention and peripheral vasoconstriction, thereby increasing the amount of fluid in the vascular space and improving blood pressure and cardiac output. Depending on the severity of the insult, variable amounts of fluid will shift from the interstitial tissues into the vascular compartment. The spleen also releases some red blood cells that are normally sequestered there to augment the oxygen-carrying capacity of the blood. The overall response of the initial compensatory mechanisms is to increase the preload (venous return), stroke volume, and heart

rate to ensure adequate cardiac output. The result is usually an increase in cardiac output and myocardial oxygen demand.

Documentation & Communication

The terms *shock* and *hypoperfusion* are often used interchangeably; however, the terms are not synonymous. Localized hypoperfusion, such as from arterial occlusion, is not shock.

As hypoperfusion persists, myocardial stress increases. Eventually, the above-normal compensatory mechanisms can no longer keep up with the increased oxygen demand. Myocardial function worsens, with decreased cardiac output and ejection fraction. Tissue perfusion decreases, leading to impaired cell metabolism. Often, the blood pressure decreases, especially in progressive hypoperfusion. Fluid may leak from the blood vessels, causing systemic and pulmonary edema. At this point, other signs of hypoperfusion may be present, such as dyspnea, dusky skin, low blood pressure, oliguria, and impaired mentation.

Shock is an abnormal state associated with inadequate oxygen and nutrient delivery to the metabolic apparatus of the cell, resulting in impairment of cellular metabolism and, ultimately, inadequate perfusion of vital organs. After a certain level of tissue hypoperfusion has been reached, cell damage proceeds in a similar manner regardless of the type of initial insult. Impairment of cellular metabolism prevents the body from properly using oxygen and glucose at the cellular level. Cells revert to anaerobic metabolism, which causes increased lactic acid production and metabolic acidosis, decreased oxygen affinity for hemoglobin, decreased ATP production, changes in cellular electrolyte levels, cellular edema, and release of lysosomal enzymes. Glucose impairment raises the level of blood glucose as catecholamines and cortisol are released. In addition, fat breakdown (lipolysis) with ketone formation may occur.

Types of Shock

Shock can occur as a result of inadequacy of the central circulation (the heart and the great vessels) or of the peripheral circulation (the remaining vessels,

including the microscopic circulation—that is, arterioles, venules, and capillaries. From a mechanistic approach, two types of shock are distinguished: central and peripheral. **Central shock** consists of cardiogenic shock and obstructive shock. **Peripheral shock** includes hypovolemic shock and distributive shock.

The following sections provide an overview of types of shock. These topics are also discussed in later chapters.

Central Shock

Cardiogenic Shock

Cardiogenic shock occurs when the heart cannot circulate enough blood to maintain adequate peripheral oxygen delivery. In the case of ischemic heart disease, this condition typically occurs when there is a loss of 40% or more of functioning myocardium. The most common cause of cardiogenic shock is myocardial infarction, as a single event or by cumulative damage. Other forms of cardiac dysfunction may also precipitate cardiogenic shock, such as a large ventricular septal defect or dysrhythmias. (See Chapter 18, *Cardiovascular Emergencies*, for more on dysrhythmias.)

Obstructive Shock

Obstructive shock occurs when blood flow becomes blocked in the heart or great vessels. In **pericardial tamponade** (**FIGURE 8-9**), diastolic filling of the right and left ventricles of the heart is impaired because of relatively large amounts of fluid in the pericardial sac surrounding the heart. Decreased ventricular filling associated with pericardial tamponade leads to a decrease in the cardiac output. Aortic dissection leads to a false lumen (aortic opening), with loss of normal blood flow (**FIGURE 8-10**). A left atrial tumor may obstruct flow between the atrium and

Words of Wisdom

Neurogenic shock can involve bradycardia if the injury is in the high thoracic spinal cord because of disruption in the sympathetic autonomic pathway. Cardiogenic shock can involve bradycardia when myocardial infarction is the cause and there is a disruption in the electrophysiologic pathway.

FIGURE 8-9 Cardiac tamponade following myocardial rupture. **A.** Distended pericardial sac. **B.** Pericardial sac opened, showing clotted blood surrounding the heart, which compressed the heart and prevented filling of the right ventricle in diastole.

FIGURE 8-10 Sites of thoracic aortic dissection. **A.** A tear in the ascending aorta causes proximal and distal dissection. **B.** A tear in the descending aorta may cause extensive distal dissection.

© Jones & Bartlett Learning.

ventricle and decrease cardiac output. Obstruction of the superior or inferior vena cava (vena cava syndrome) decreases cardiac output by decreasing venous return. A large pulmonary embolus (blood

clot in the lung) or a tension pneumothorax (lung collapse) may prevent adequate blood flow to the lungs, resulting in inadequate venous return to the left side of the heart.

Peripheral Shock

Hypovolemic Shock

In **hypovolemic shock**, the circulating blood volume is insufficient to deliver adequate oxygen and nutrients to the body. Two types of hypovolemic shock—exogenous and endogenous—are possible, depending on where the fluid loss occurs. The most common type of exogenous hypovolemic shock is external bleeding (such as from an open wound); it may also result from loss of plasma volume caused by diarrhea or vomiting. Endogenous hypovolemic shock occurs when the fluid loss is contained within the body.

Distributive Shock

Distributive shock occurs when there is widespread dilation of the resistance vessels (small arterioles), the capacitance vessels (small venules), or both. The circulating blood volume then pools in the expanded vascular beds, and tissue perfusion decreases. The three most common types of distributive shock are anaphylactic shock, septic shock, and neurogenic shock.

Anaphylactic shock (also called anaphylaxis) occurs when histamine and other vasodilator proteins are released on exposure to an **allergen** (any substance that causes a hypersensitivity reaction). Anaphylactic shock is also accompanied by wheezing and **urticaria** (hives). The result is widespread vasodilation that causes distributive shock and blood vessels that continue to leak. Fluid leaks out of the blood vessels into the interstitial spaces, resulting in intravascular hypovolemia.

Septic shock occurs as a result of widespread infection, usually bacterial. Complex interactions occur between the bacterial invader and the body's defense systems. Initially, the body's own defense

mechanisms may keep the infection at bay. If the normal immune mechanisms become overwhelmed, then the body produces a multitude of substances that cause vasodilation and decreased cardiac output. If left untreated, then the result is multiple organ dysfunction syndrome (discussed later) and often death.

Words of Wisdom

Typically, the earliest signs of shock are restlessness and anxiety. The patient looks scared!

Neurogenic shock usually results from spinal cord injury. The effect is loss of normal sympathetic nervous system tone and vasodilation (**FIGURE 8-11**). Patients often have fluid-refractory hypotension as a result of the degree of vasodilation.

Management of Shock

Most types of shock are characterized by reduced cardiac output, circulatory insufficiency, and rapid heartbeat. Although low blood pressure is

FIGURE 8-11 Damage to the spinal cord can cause substantial injury to the part of the nervous system that controls the size and muscle tone of blood vessels. If the smooth muscle in the blood vessels is cut off from its impulses to contract, then the vessels dilate widely, increasing the size and capacity of the vascular system. The blood in the body can no longer fill the enlarged vessels, which results in inadequate perfusion and neurogenic shock.

© Jones & Bartlett Learning.

Words of Wisdom

In anaphylaxis, interstitial fluid may cause substantial swelling. In some cases, this swelling may occlude the upper airway, resulting in a life-threatening condition manifesting as the adventitious sound of stridor. Recurrent large areas of subcutaneous edema of sudden onset, usually disappearing within 24 hours, are called angioedema. This condition is seen frequently as a result of allergy to food or drugs, such as angiotensin-converting enzyme inhibitors.

classically associated with shock, it is a late sign, especially in children.

Words of Wisdom

A possible exception to the standard use of IV fluid therapy to treat shock is hypovolemic shock caused by ongoing bleeding. Permissive hypotension, in which the provider attempts to achieve an appropriate mental status and the presence of peripheral pulses, may be safer than attempting restoration of normotension, which may aggravate ongoing bleeding. As always, follow your local protocols.

Clinically, determining the presence or absence of shock requires you to evaluate the presence and volume of the peripheral pulses and assess end-organ perfusion and function. Strength of the peripheral pulses is related to stroke volume of the heart and pulse pressures. Peripheral pulses should be readily palpable if the person is not in shock, although cold environments or obesity may compromise the presence or strength of these pulses. Normal skin perfusion is indicated by warm, dry, pink extremities, fingers, and toes, whereas a slow, delayed, or prolonged **capillary refill time** indicates shock (although this technique is more reliable in children). To test the capillary refill time, briefly squeeze the toenail or fingernail, and then observe the time it takes for color to return. A normal capillary refill time is less than 2 seconds after blanching of the toe or finger, whereas a person in shock may have a capillary refill time of more than 2 seconds. Mottling, pallor, peripheral or central cyanosis, and delayed capillary refill may signal the presence of shock, whereas altered mental status indicates inadequate brain tissue perfusion. The accuracy of a capillary refill measurement decreases in patients older than 6 years; it is most useful in young children but not as useful in the adult population.

Measuring ETCO_2 may also be useful to the astute clinician. Although ETCO_2 provides valuable information regarding the respiratory and ventilatory status of the patient, you can also interpret the effectiveness of perfusion in your patient based on changes in capnography and capnometry. As perfusion decreases, the amount of carbon dioxide returned to the lungs also decreases, causing ETCO_2 levels to decrease (**FIGURE 8-12**). Carbon dioxide is one of the by-products of cellular metabolism, so decreasing levels of

A

ETCO_2 are an early indicator of shock. Low ETCO_2 levels (below 35 mm Hg) combined with other signs and symptoms of shock such as hypotension and altered mental status are ominous clinical findings.

Treatment primarily addresses the underlying condition. See Chapter 27, *Bleeding*, for more information on hypovolemic shock as a result of hemorrhage.

Multiple Organ Dysfunction Syndrome

Multiple organ dysfunction syndrome (MODS), first described in 1975, is a progressive condition that occurs in some critically ill patients. It is characterized by the concurrent failure of two or more organs

or organ systems that were initially unharmed by the acute disorder or injury that caused the patient's initial illness. Six organ systems are surveyed in diagnosing MODS: respiratory, hepatic, renal, hematologic, neurologic, and cardiovascular. Each system is assigned a score to determine the patient's overall risk. For example, the Glasgow Coma Scale score is used to score the patient's neurologic system function. Although MODS may begin in one physiologic system, the disease process often progresses in a cyclical method, including multiple organ systems and complicating factors throughout its course.

In MODS, the overall mortality rate varies widely depending on the underlying etiology and ensuing diagnosis and treatment. Despite the inevitability its name suggests, the condition is often reversible, particularly in patients who were healthy before the physiologic insult occurred.¹⁰ MODS is the major cause of death following sepsis, trauma, and burn injuries, with mortality rates of up to 75%.¹⁰

Primary MODS is directly attributable to an initial insult, such as a pulmonary contusion from embolization of fat and marrow contents as a result of a femur fracture. Secondary MODS is a slower, more progressive organ dysfunction that results from a systemic inflammatory response.

Secondary MODS occurs when injury or infection (septic shock) triggers a massive systemic immune, inflammatory, and coagulation response accompanied by the release of toxins that are present inside bacterial cells. Overactivating the complement system further increases inflammation and cellular damage. Vascular endothelial damage triggers overactivation of the coagulation system, which leads to uncontrolled coagulation in the venules and arterioles. This coagulation, in turn, causes microvascular thrombus formation and tissue ischemia. In addition, MODS activates the kallikrein-kinin system, stimulating the release of bradykinin, a potent vasodilator. Kallikrein is an inactive enzyme of the pancreas. When activated, kallikrein can dilate blood vessels, influence blood pressure, modulate salt and water excretion by the kidneys, and influence cardiac remodeling after acute myocardial infarction (AMI). Bradykinin increases vascular permeability, dilates blood vessels, contracts smooth muscle, and causes pain when injected into the skin. Vasodilation leads to tissue hypoperfusion and may also contribute to hypotension.

The net outcome of the activation of these systems is maldistribution of systemic and organ blood flow. Often, the body attempts to compensate for this problem by accelerating tissue metabolism. The result is an imbalance in oxygen supply and demand that causes tissue hypoxia, initiating a cascade of ill effects including tissue hypoperfusion, exhaustion of the cells' fuel supply (ATP), metabolic failure, lysosome breakdown, anaerobic metabolism, and acidosis and impaired cellular function.

Typically, MODS develops hours or days following resuscitation. The signs and symptoms include hypotension, insufficient tissue perfusion, uncontrollable bleeding (coagulopathy), and multisystem organ failure. A low-grade fever may develop from the inflammatory response, along with tachycardia and dyspnea. Patients may also be difficult to oxygenate because of acute lung injury and acute respiratory distress syndrome.

During a 14- to 21-day period, renal and liver failure can develop in patients with MODS, along with collapse of the gastrointestinal and immune systems. The kidneys depend on adequate perfusion pressure. After the mean arterial pressure drops, kidney function decreases. Oliguria occurs early in shock. Renal studies show elevated blood urea nitrogen and creatinine levels. Many patients require continuous bedside dialysis.

The liver is a complex organ with a key role in excreting wastes and toxins. Adequate liver function is also essential for the synthesis of blood proteins and coagulation proteins, as well as the storage of glycogen, iron, and vitamins. Patients with MODS have elevated levels of total bilirubin and of the liver enzymes aspartate aminotransferase and alanine aminotransferase. Unfortunately, there are no definitive treatments for liver failure. Treatment focuses on minimizing the effects of liver damage.

The brain, adrenal glands, and heart are also affected early in MODS. The level of consciousness deteriorates quickly in hypoxic states, but it declines precipitously in patients with MODS. Cerebral hypoxia and subsequent ischemia can cause permanent deficits as a result of anoxic brain injury.

As the heart struggles to maintain arterial perfusion pressure, it too becomes hypoxic. Hypotension cannot be controlled despite the administration of

fluids and vasopressors. Compensatory tachycardia consumes even more oxygen, and dysrhythmias such as bradycardia, ventricular tachycardia, and ventricular fibrillation develop. Cardiovascular collapse and death typically occur within days to weeks of the initial insult.

The Body's Self-Defense Mechanisms

The **immune system** includes all structures and processes associated with the body's defense against foreign substances and disease-causing agents. The body has three lines of defense: anatomic barriers, the inflammatory response, and the immune response.

Anatomic Barriers

Several anatomic barriers decrease the chances of foreign substances invading the body. The skin serves as a major deterrent. Hairs in the upper respiratory tract (the nose) and the lining of the lower respiratory tract (cilia-covered epithelial cells) help repel foreign matter, especially small particles and some bacteria. Acid in the stomach prevents many infectious agents from entering the body via the gastrointestinal tract.

Immune Response

The **immune response** is the body's defense reaction to any substance it recognizes as foreign. This response is often directed toward invading microbes, such as bacteria or viruses. It is also triggered by foreign bodies, such as a splinter, and even abnormal cell growths, such as tumors. The immune response involves only one type of white blood cell, called lymphocytes.

Not all invaders can be destroyed by the body's immune system. In some cases, the best compromise the body can reach is to control the damage and keep the invader from spreading. Often, the immune system succeeds in preventing severe disease following infection. When the normal systems become overwhelmed or fail, serious disease occurs.

The body responds to different kinds of immune challenges in remarkably similar ways. Although the details depend on the particular challenge, the basic pattern is the same—the innate response starts first and is then reinforced by the more specific acquired response. These two pathways are interconnected.

Consider what happens when bacteria enter the body. If the bacteria are not encapsulated, then macrophages begin immediately to ingest the

YOU are the Provider

Part 3

Your partner is administering high-flow oxygen, attaching the ETCO₂, assessing vital signs, and setting up an IV line. You auscultate lung sounds and hear little air movement. You hear coarse crackles (formally known as rales) bilaterally in all fields. The patient coughs, and you notice pink, frothy sputum. You ask your partner to assess the medications on the side table while you establish the IV line.

Recording Time: 2 Minutes

Respirations	22 breaths/min; shallow
Pulse	110 beats/min
Skin	Cool, moist, and pale
Blood pressure	140/90 mm Hg
Oxygen saturation (SpO₂)	89% before high-flow oxygen administration
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

- On the basis of what you know about physiology, what is causing the pink, frothy sputum?
- How do you account for the decreased SpO₂ level?

bacteria. If the bacteria are encapsulated, then antibodies (opsonins) must coat the capsule before it can be ingested by phagocytes.

Components of the cell wall then activate the complement system. Some components of the activated complement system, termed **chemotaxins**, attract leukocytes from the circulation to help fight the infection. The complement cascade ends with the formation of a set of proteins called the **membrane attack complex**. These molecules insert themselves into the bacterial membrane, weakening those areas in the membrane. Ions and water enter the cell through the weakened areas, leading to lysis of the bacterium (a chemical process that does not involve immune cells).

If antibodies to the bacteria are already present in the body, then these antibodies will assist the

innate response by acting as opsonins and neutralizing bacterial toxins. Although it often takes several days, memory B cells attracted to the infection site will be activated if a recognized antigen is encountered. If the infection is new to the body—that is, preexisting antibodies are not present—then B cells will be activated. Combined with **helper T cells** and cytokine release, antibodies are produced and memory B and T cells are formed.

TABLE 8-4 describes the types of immune system cells.

Characteristics of the Immune Response

The native and acquired immune responses protect the body from infectious agents such as viruses

TABLE 8-4 Immune System Cells	
Type of Cell	Description
Basophil	A type of white blood cell that releases histamine during inflammation.
Eosinophil	A type of white blood cell that phagocytizes the antigen-antibody complex; attacks parasites.
Neutrophil	A type of white blood cell that phagocytizes bacteria.
Monocyte	A type of white blood cell that phagocytizes bacteria, dead cells, and cellular debris.
Lymphocyte	A type of white blood cell involved in immune protection; attacks cells directly or produces antibodies.
Macrophages	White blood cells within tissues; produced by differentiation of monocytes. Functions include phagocytosis and stimulating lymphocytes and other immune cells to respond to pathogens; one of the first lines of defense in the inflammatory process.
Mast cells	Cells that are found in the connective tissues, beneath the skin, in the gastrointestinal mucosa, and in the mucosal membranes of the respiratory system. Functions relate to allergic reactions, immunity, and wound healing.
Plasma cells	White blood cells that develop from B cells and produce large volumes of specific antibodies.
B cells (B lymphocytes)	Cells that mature in the bone marrow, where they differentiate into memory cells or immunoglobulin-secreting (antibody) cells. Functions include eliminating bacteria, neutralizing bacterial toxins, preventing viral reinfection, and producing immediate inflammatory response.
Helper B cell	A type of regulator cell that activates B cells to produce antibodies.
Memory B cell	A type of B cell that aids in the quick response to subsequent exposures to an antigen because memory cells recall the antigen as foreign. These cells rapidly produce antibodies.
T cells (T lymphocytes)	Cells that are produced in the bone marrow and mature in the thymus. Two major types work to destroy antigens—regulator cells and effector cells.
Killer T cell	A type of T cell that destroys cells infected with viruses by releasing lymphokines that destroy cell walls; also called cytotoxic or effector cells.

and bacteria and from foreign substances that have gained access to the body through the skin or the lining of internal organs.

Natural immunity, also called native immunity, is a nonspecific cellular and humoral (antibody) response that operates as the first line of defense against pathogens. Most natural immunity is associated with the initial inflammatory response.

Acquired immunity (also called adaptive immunity) is a highly specific, inducible, discriminatory method by which armies of cells respond to an immune stimulant, such that the immune system will never fail to recognize the same stimulant when it is subsequently encountered, even years later. It arises when the body is exposed to a foreign substance or disease and produces antibodies to the invader. Passively acquired immunity is the receipt of preformed antibodies to fight or prevent infection. Examples of passively acquired immunity include the transplacental passage of antibodies and the passage of antibodies in colostrum (the mother's initial breast milk to her infant), which protects the infant until the immune system matures sufficiently to take over. The injection of immunoglobulin (a concentrated form of antibodies obtained from donors) is also a form of passively acquired immunity.

The primary (initial) immune response takes place during the first exposure to an **antigen** (a foreign substance; a neoantigen is an antigen associated with cancerous cells). Clinical symptoms may not be apparent. Sometimes, the body's initial response is to produce an antibody that triggers symptoms on subsequent exposures. The secondary (amnesic) immune response occurs with reexposure to a foreign substance. The body has already developed a sort of memory for that substance, so a reaction occurs on reexposure to the substance.

An **antibody** binds a specific antigen so the complex can attach itself to specialized immune cells that ingest the complex to destroy it or release biologic mediators such as histamine to induce an allergic or inflammatory response. The specific features of the antigen-antibody interaction depend on the foreign substance involved (**FIGURE 8-13**).

An **immunogen** is an antigen capable of generating an immune response. Thus, an immunogen is an antigen, but an antigen is not necessarily an immunogen. Antigens and immunogens can be categorized by size. Proteins, polysaccharides,

and nucleic acids are larger, whereas amino acids, monosaccharides, and fatty acids are smaller. A **hapten** is a substance that normally does not stimulate an immune response but that can be combined with an antigen and later initiate a specific antibody response on its own.

Humoral Immune Response

In **humoral immunity**, B-cell lymphocytes produce antibodies called immunoglobulins, which recognize a specific antigen and then react with it, as shown in **FIGURE 8-14**. This differs from cell-mediated immunity, discussed later, in which macrophages and T cells attack and destroy pathogens or foreign substances.

B Lymphocytes

Like all blood cells, B cells are born in the bone marrow, where they are descended from stem cells. The clonal selection theory holds that each B cell makes antibodies that have only one type of antigen-binding region and, therefore, are specific for a particular antigen, known as the cognate antigen. Antibodies are found on the surface of B cells, where they are able to recognize the presence of their cognate antigens. When a B cell recognizes the cognate antigen, it proliferates to make more identical B cells in an exponential manner, each of which can make antibodies that recognize the same antigen.

For B cells to produce antibodies, B cells must first be activated. The most common way this occurs is via helper T cells (**FIGURE 8-15**):

1. A macrophage engulfs the antigen via phagocytosis. It digests the antigen, pushing the discarded particles to the cell surface. These remnants interact with the B cell and a helper T cell.
2. The antigen binds to the B cell and the helper T cell, activating both.
3. The activated helper T cell secretes a lymphokine, a substance that stimulates the B cells to produce a clone. A clone is a group of identical cells formed from the same parent cell. The clone comprises two types of identical cells that have different functions: plasma cells, which make the antibodies, and memory cells, which remember the initial encounter with the antigen.

**FIGURE 8-13** How antibodies work.

© Jones & Bartlett Learning.

The human body distinguishes between foreign substances and its own cells and tissues by means of the major histocompatibility complex, a group of genes located on a single chromosome that permits a person who is capable of generating an immune response to distinguish *self* from *nonself* (namely, what is foreign). The human leukocyte antigen gene complex is the human major histocompatibility complex and is present in all nucleated human cells. It encodes for numerous antigens that are unique to a person. When the immune system encounters

these particular antigens, it recognizes them as self, and no immune response occurs.

Immunoglobulins

The antibodies secreted by B cells are called **immunoglobulins** (this text uses the terms *immunoglobulins* and *antibodies* interchangeably, unless otherwise stated). These Y-shaped proteins consist of a crystallizable fragment (Fc) portion and two antigen-binding fragment (Fab) regions that bind only a specific antigen. The basic antibody

FIGURE 8-14 B-cell activation. Immunocompetent B cells are stimulated by the presence of an antigen, producing an intermediate cell, the lymphoblast. The lymphoblasts divide, producing plasma cells and some memory B cells. Memory B cells respond to subsequent antigen encroachment, yielding a rapid secondary response.

FIGURE 8-15 Interaction of cell-mediated and humoral immunity. A macrophage presents processed antigen fragments to the T lymphocyte. The B lymphocyte processes the intact antigen and displays fragments of the same antigen on its cell membrane. The T lymphocyte, which has responded to the same antigen, stimulates the B lymphocyte to proliferate, mature into plasma cells, and make antibodies.

molecule has four chains linked into a Y shape. Each side of the Y is identical, with one light chain attached to one heavy chain **FIGURE 8-16**. The two arms, or Fab regions, contain antigen-binding sites. The stem, or Fc region, determines which of the five immunoglobulin classes an antibody belongs to (**FIGURE 8-17**).

Most antibodies are found in the plasma. Antibodies make up about 20% of the plasma proteins in a healthy person. Antibodies make antigens more visible to the immune system in three ways:

- Antibodies act as opsonins. In **opsonization**, an antibody coats an antigen to facilitate its

FIGURE 8-16 Structure of an immunoglobulin molecule.

© Jones & Bartlett Learning.

FIGURE 8-17 General structure of an antibody. Note that immunoglobulin G (IgG) is a monomer; it is one molecule. Immunoglobulin M (IgM) is a pentamer; it is a cluster of five antibodies and is effective in combining with foreign antigens. Also note that the antigen fits exactly into the antigen binding site (if it did not, it would not be able to bind). Antigen binding sites therefore have different structures, depending on the antigen to which they are designed to bind.

© Jones & Bartlett Learning.

recognition by immune cells. Antibodies are not toxic, but they label antigens so other immune cells will attack them.

- Antibodies cause antigens to clump for easier phagocytosis.
- Antibodies bind to and inactivate some toxins produced by bacteria. Macrophages can then ingest and destroy the inactivated toxins.

Antibodies are divided into five general classes of immunoglobulins (**TABLE 8-5**).

Cell-Mediated Immune Response

Cell-mediated immunity is characterized by the formation of a population of lymphocytes that can attack and destroy foreign material. It is the main defense against viruses, fungi, parasites, and some bacteria. Cell-mediated immunity is the mechanism by which the body rejects transplanted organs

TABLE 8-5 General Classes of Immunoglobulins

Class	Description
IgG	The most common immunoglobulin. Accounts for 75% of the antibodies in the blood. Found in lymph, synovial fluid, peritoneal fluid, cerebrospinal fluid, and breast milk. IgG is the only immunoglobulin that crosses the placenta, giving infants immunity during the first few months of life.
IgA	Accounts for 15% of the antibodies in the blood. Also found in tears, saliva, respiratory tract secretions, and the stomach. IgA combines with a protein in the mucosa and defends body surfaces against invading microorganisms.
IgM	Accounts for 5% to 10% of the antibodies in the blood and is the dominant antibody in ABO (blood type) incompatibilities. IgM is the initial antibody formed in most infections.
IgE	Accounts for less than 1% of the antibodies in the blood and is associated with allergic reactions. When mast cell receptors combine with IgE and antigen, the mast cells degranulate and release chemical mediators such as histamine.
IgD	Accounts for less than 1% of the antibodies in the blood. The physiologic role of IgD is unclear.

© Jones & Bartlett Learning.

and eliminates the abnormal cells that sometimes arise spontaneously in cell division.

In cell-mediated immunity, T-cell lymphocytes recognize antigens and contribute to the immune response in two major ways: (1) by secreting cytokines that attract other cells or (2) by becoming cytotoxic and killing infected or abnormal cells. There are five subgroups of T cells:

1. **Killer T cells.** Killer T cells (also called cytotoxic T cells) destroy the antigen. Killer T cells help rid the body of cells that have been infected by viruses and cells that have been transformed into cancer cells. Killer T cells are

also responsible for the rejection of tissue and organ grafts.

2. **Helper T cells.** Helper T cells activate many immune cells, including B cells and other T cells (also called T4 or CD4⁺ cells).
3. **Suppressor T cells.** Suppressor T cells (also called T8 or CD8⁺ cells) suppress the activity of other lymphocytes so they do not destroy normal tissue.
4. **Memory T cells.** Memory T cells remember the reaction for the next time it is needed.
5. **Lymphokine-producing cells.** Secreted by lymphocytes, these cells work to damage cells; for example, lymphokines destroy cells that have been infected with a virus.

During the cell-mediated response, macrophages ingest pathogens. When a macrophage digests a pathogen, it releases small particles of antigen. This antigen pushes its way to the macrophage surface, where it is recognized by specific T cells. Other T cells, such as helper T cells and killer T cells, bind to the antigen and macrophage, destroying the invader.

Special Populations

T-cell and B-cell function is often deficient in older adults. Depressed lymphocyte function is accompanied by a decrease in macrophage activity. Therefore, older adults are more susceptible to infections and recover more slowly. In addition, older adults have an increased level of **autoantibodies** (antibodies directed against the self), which partly explains why older adults are susceptible to autoimmune disease.

Inflammatory Response

The inflammatory response is a response of the tissues of the body to irritation or injury. It is characterized by pain, swelling, redness, and heat. White blood cells of various types are a major component of this response.

The inflammatory reaction and the immune response are independent processes, although the processes often occur simultaneously. Inflammation can be present without activation of the immune response, and vice versa. Inflammation

is a dynamic process that, when initiated, triggers a complex cascade involving local and systemic events. The two most common causes of inflammation are infection (such as bacterial or viral) and injury.

Acute Inflammation

The acute inflammatory response involves vascular and cellular components. Initially, the arterioles constrict in an attempt to limit blood loss, but then dilate, allowing an influx of blood under increased pressure. This leads to increased intravascular pressure and causes the blood vessel to expand; as in a balloon that is being inflated, the vessel walls become thinner. The higher pressure combined with increased vessel wall permeability causes fluid to leak into the interstitial spaces (edema). When enough fluid has escaped into the surrounding area and the intravascular pressure has been released, the vessel wall contracts and the flow slows, leading to pooling of blood in the capillaries.

A variety of blood cells participate in tissue inflammatory reactions: white blood cells (leukocytes), platelets, mast cells, and plasma cells (B lymphocytes that create antibodies). Specific cell types include neutrophils, monocytes, lymphocytes, eosinophils, basophils, and activated platelets. Chemical mediators, primarily produced by the mast cells, account for the vascular and cellular events that occur during the acute inflammatory response. Cell-derived mediators include histamine, arachidonic acid derivatives, and cytokines such as interleukins and tumor necrosis factor.

Words of Wisdom

Because corticosteroids can decrease the initial inflammatory response, which is a necessary part of wound healing, this can increase the risk of wound infection. This is an important consideration when obtaining the history of patients with diabetes because of their propensity to develop infections in inadequately healing wounds.

Mast Cells

Mast cells have a major role in inflammation. During inflammation, mast cells degranulate and release a variety of substances. The primary stimuli

for the degranulation of mast cells during the inflammatory response are physical injury (trauma), chemical agents (for example, bacterial toxins), and immunologic substances (for example, interaction of an antigen and an immunoglobulin E (IgE) antibody).

After degranulation, mast cells release **vasoactive amines**. The most important of these substances, **histamine** and **serotonin**, increase vascular permeability; cause vasodilation; and can cause bronchoconstriction, nausea, and vomiting. Because histamine is a preformed vasodepressor amine stored in mast cells, it can be released quickly, so its actions are seen early in the inflammatory response. Mast cells also synthesize chemotactic factors that attract neutrophils (neutrophil chemotactic factor) and eosinophils (eosinophilic chemotactic factor).

Mast cells also synthesize leukotrienes. **Leukotrienes**—also known as slow-reacting substances of anaphylaxis—are a family of biologically active compounds derived from arachidonic acid. The clinically important leukotrienes participate in host defense reactions and pathophysiologic conditions that AEMTs commonly see in the field, such as immediate hypersensitivity and inflammation. Leukotrienes have potent actions on many parts of the body, including the cardiovascular, pulmonary, immune, and central nervous systems and the gastrointestinal tract.

Leukotrienes are primarily endogenous mediators of inflammation. They contribute to the signs and symptoms seen in acute inflammatory responses, including responses resulting from the interaction of allergens with IgE antibodies on mast cells. Certain leukotrienes are bronchoconstrictors, stimulate airway mucus secretion, and are very effective at increasing the permeability of postcapillary venules (including those in the bronchial circulation), thereby causing plasma protein exudation (oozing out of the tissue) and edema. Certain leukotrienes may also promote eosinophil migration into the airways of animals and people with asthma, and they may also increase bronchial hyperresponsiveness through an action on sensory nerves.

Finally, mast cells synthesize **prostaglandins**. These substances, which are derived from arachidonic acid, comprise a group of about 20 lipids that are composed of modified fatty acids attached to a five-member ring. Prostaglandins are found in

many vertebrate tissues, where they act as messengers in reproduction, the inflammatory response to infection, and pain perception. Aspirin and nonsteroidal anti-inflammatory drugs inhibit prostaglandin synthesis, reducing inflammation and pain.

Plasma Protein Systems

There are plasma-derived mediators that modulate the inflammatory process; these are called plasma protein systems. They include the complement system, the coagulation (clotting) system, and the kinin system. The interaction of these systems is vital to a normal inflammatory response. Each system consists of a cascade of biochemical reactions such that as one compound is produced, it catalyzes the formation of the next compound—similar to knocking over a line of dominoes.

- **Complement system.** The **complement system** is a group of plasma proteins that attract white blood cells to sites of inflammation, activate white blood cells, and directly destroy cells. The central compound in this complement cascade is called C3.
- **Coagulation system.** The **coagulation system** serves a vital role in the formation of blood clots in blood vessels. Inflammation triggers the coagulation cascade, initiating a complex series of reactions that encourage fibrin formation. **Fibrin** is the protein that polymerizes (bonds) to form the fibrous component of a blood clot. The various coagulation factors are counterbalanced by a variety of inhibitors, so the coagulation is restricted to one area. Simultaneously, the **fibrinolysis cascade** is activated to dissolve the fibrin and create fibrin split products (namely, fragments of the dissolving clot).
- **Kinin system.** The **kinin system** leads to the formation of the vasoactive protein bradykinin from kallikrein. Kallikrein is an enzyme that is normally found in blood plasma, urine, and body tissue in an inactive state. When kallikrein becomes activated, it can dilate blood vessels, influence blood pressure, modulate salt and water excretion by the kidneys, and influence cardiac remodeling after AMI. Bradykinin increases vascular permeability, dilates blood vessels, contracts smooth muscle, and causes pain when injected into the skin.

Cellular Components of Inflammation

The goal of the cellular components of the acute inflammatory response is for inflammatory cells—namely, **polymorphonuclear neutrophils (PMNs)**—to arrive at the sites in the tissue where they are needed. This process involves two major stages: an intravascular phase and an extravascular phase. During the intravascular phase, leukocytes move to the sides of blood vessels and attach to the endothelial cells. During the extravascular phase, leukocytes travel outside of the blood vessels to the site of inflammation and kill organisms. The cellular event sequence is as follows:

1. **Margination.** Loss of fluid from the blood vessels into the inflamed or infected tissue gives the blood that remains in the vessels increased viscosity, which slows the flow of blood and produces stasis. PMNs, which usually travel toward the center of the vessel, settle toward the sides as the blood flow slows. As stasis develops, leukocytes also move (marginate) toward the sides of the vessels, where they bump into the endothelial cells and bind to them. Stress can lead to demargination of some white blood cells, which stimulates the bone marrow to produce more, in turn increasing the white blood cell count.
2. **Activation.** Mediators of inflammation trigger the appearance of selectins and integrins on the surfaces of endothelial cells and PMNs, respectively.
3. **Adhesion.** PMNs attach to endothelial cells, as mediated by selectins and integrins.
4. **Transmigration (diapedesis).** The PMNs permeate the vessel wall, passing into the interstitial space.
5. **Chemotaxis.** The PMNs move toward the site of inflammation in response to chemotactic factors released by bacteria or formed from activated complement, chemokines, or arachidonic acid derivatives (such as leukotrienes) in response to cell injury.

FIGURE 8-18 illustrates the inflammatory response.

Cellular Products of Inflammation

Cytokines are products of cells that affect the function of other cells. Monocytes release monokines, and lymphocytes release lymphokines.

Interleukins include IL-1 (interleukin-1) and IL-2 (interleukin-2), which attract white blood cells to the sites of injury and bacterial invasion. **Interferon** is a protein produced by cells when they are invaded by viruses. This cytokine is released into the bloodstream or intercellular fluid to induce healthy cells to manufacture an enzyme that counters the infection.

Lymphokines stimulate leukocytes. Macrophage-activating factor stimulates macrophages to help engulf and destroy foreign substances. Migration inhibitory factor keeps white blood cells at the site of infection or injury until they can perform their designated task.

Injury Resolution and Repair

Normal wound healing involves four steps—repair of damaged tissue, removal of inflammatory debris, restoration of tissues to a normal state, and regeneration of cells. Healing after tissue injury or loss caused by inflammation depends on the type of cells that make up the affected organ. Labile cells divide continuously, so organs derived from these cells (such as skin, bone, and intestinal mucosa) heal completely. Stable cells are replaced by regeneration of remaining cells, which are stimulated to enter mitosis. These cells are found in the liver and kidney. Permanent cells, such as nerve cells and cardiac myocytes, cannot be replaced; scar tissue is formed instead.

Wounds may heal by primary or secondary intention. Healing by primary intention occurs in clean wounds with opposed margins (such as clean surgical wounds or surgically debrided wounds). First, blood fills the defect and coagulates, forming a scab—a meshlike structure composed of fibrin and fibronectin. If the inflammatory process was severe, then tissue may be destroyed and may require repair. Next, macrophages remove cellular debris and secrete growth factors. These growth factors stimulate angiogenesis and growth of fibroblasts, encouraging the formation of granulation tissue. The epithelium then regenerates, covering the surface defect. Deposition of collagen produces fibrous union. By the end of the first week, 10% of the preinjury strength is regained. Scar maturation occurs as collagen cross-linking takes place. By the end of 3 months, 80% of the normal tensile strength of the tissue has been restored.

Healing by secondary intention occurs in large, gaping or infected wounds. Wounds that heal by

**FIGURE 8-18** The inflammatory response.

© Jones & Bartlett Learning.

secondary intention have a more pronounced and prolonged inflammatory phase, causing the neutrophils to persist for days. They also have more abundant granulation tissue. Wound contraction is mediated by myofibroblasts, which help to draw the margins of the wound closer to each other as time passes.

Dysfunctional Wound Healing

Factors that can lead to dysfunctional wound healing may be local or systemic. Local factors include infection (when the body's healing efforts are diverted to fight off the cause of the infection); an inadequate blood supply (as in diabetes) that produces tissue hypoxia, which slows wound healing and may promote infection; and foreign bodies (when present in a wound, they stimulate acute and chronic inflammation, both of which interfere with wound healing).

There are several systemic factors that influence wound healing. Collagen is necessary for wound healing, but inadequate nutritional intake can lead to insufficient levels of collagen, which can result in inadequate scar formation and suppression of the immune system. Anything that interferes with epithelialization (the process during which epithelial cells begin to form a scab that protects the wound from the outside world) will prevent proper wound healing. *Wound contraction* is the process during which the size of the wound becomes smaller, as part of healing. Anything that interferes with wound contraction can also prevent healing.

Additional systemic factors that disrupt wound healing include hematologic abnormalities (proper wound healing requires the presence of adequate numbers of white blood cells). Patients who have impaired bone marrow stores of white blood cells are susceptible to infection and their wounds often heal more slowly. Diabetes and acquired immunodeficiency syndrome (AIDS) affect the cells of the immune system, which has a direct role in wound healing, and increase the likelihood of wound infection. Corticosteroids suppress the initial inflammatory response required for the proper formation of scar tissue and increase the risk of wound infection by slowing the immune system response.

Finally, if a wound separates (for example, from physical strain), this will slow down the healing process because healing needs to start over, at least to some extent.

Special Populations

Neonates and older adults often have relative impairment of their immune systems, potentially slowing their inflammatory responses. Consequently, signs of inflammation may be more subtle in these populations. In addition, wound healing often takes longer, especially in older patients. The immune system is not fully developed until a child is between 2 and 3 years old; therefore, when you treat fever in younger children, you must be aggressive and thorough. Many experts recommend hospital admission for a temperature greater than 100.4°F (38°C) in a child younger than 3 months.

Chronic Inflammatory Responses

Chronic inflammatory responses are usually caused by an unsuccessful acute inflammatory response to a foreign body, a persistent infection, or the presence of an antigen. They are associated with an infiltrate (pus) containing monocytes and lymphocytes and usually involve tissue destruction and repair (or scar formation). The vascular events are similar to those that occur in acute inflammation but also include the growth of new blood vessels (a process known as **angiogenesis**).

Variances in Immunity and Inflammation

Hypersensitivity

Hypersensitivity is any response of the body to any substance to which a patient has increased sensitivity. It is a generic term for a variety of reactions.

Allergy is a hypersensitivity reaction to the presence of an agent (allergen). **Autoimmunity** is the production of antibodies or T cells that work against the tissues of one's own body, producing hypersensitivity reactions or autoimmune disease (as in systemic lupus erythematosus [SLE]). **Isoimmunity** is the formation of T cells or antibodies directed against the antigens on another person's cells (typically after the transplantation of an organ or tissues). A blood transfusion reaction is an example of an isoimmune reaction to another person's red blood cells. The destruction of cells by antibodies or T cells may be an autoimmune or an isoimmune reaction.

Types of Hypersensitivity Reactions

A hypersensitivity reaction may be immediate, occurring within seconds to minutes, or delayed, occurring hours to days after exposure to an antigen. The speed of symptom evolution depends on the antigen and the type of response the body mounts against it. Hypersensitivity reactions are typically classified based on how the immune system caused the injury. **TABLE 8-6** describes the four types of injuries.

Type I: Immediate Hypersensitivity Reactions

A type I hypersensitivity reaction is an acute reaction that occurs in response to a stimulus (such as a bee sting, penicillin, or shellfish). The mechanism involves interaction between the stimulus (antigen) and a preformed antibody of the IgE type. At first exposure to a specific antigen, specific IgE antibodies bind to mast cells via the nonspecific region (Fc) portion. On secondary exposure to the same antigen, these bound antibodies are cross-linked by the antigen, resulting in degranulation of the mast cell and release of histamine and other mediators (**FIGURE 8-19**). The released histamine feeds back on mast cells and eosinophils, leading to the release of additional histamine and other

mediators. The severity of the symptoms that develop in a specific patient depends on the extent of mediator release.

The degree of severity of hypersensitivity reactions varies from severe, life-threatening reactions, such as anaphylaxis, to milder reactions, such as allergic rhinitis (edema and irritation of the nasal mucosa), bronchial asthma (bronchial constriction, mucus production, and airway inflammation), wheal and flare (such as an insect bite leading to vasodilation and swelling), and mild food allergy (leading to diarrhea, gastrointestinal distress, and vomiting). A propensity to type I reactions may be diagnosed through skin tests (such as the patch test and scratch test) and other laboratory procedures (measurement of specific IgE antibody levels). Treatment is avoidance of the antigen, but desensitizing injections may be helpful in severe cases.

It is impossible to predict the severity of any given reaction. If a person has had a severe reaction in the past, then he or she is at an increased risk for another one with subsequent antigen exposures. Always assume an IgE-mediated reaction could rapidly become a life-threatening event. These reactions need to be treated quickly in the field, and most prehospital providers are trained to administer epinephrine by using an EpiPen auto-injector or by giving a subcutaneous injection.

TABLE 8-6 Mechanisms of Immunologic Injury

Type	Mechanism	Examples
I: Immediate hypersensitivity	IgE antibodies fix to mast cells and basophils. Later contact with a sensitizing antigen triggers mediator release and clinical manifestations.	Localized response: hay fever, food allergy Systemic response: bee sting, penicillin, anaphylaxis
II: Cytotoxic hypersensitivity reactions	Antibody binds to cell or tissue antigen, and complement is activated, which damages cell, causes inflammation, and promotes destruction of antibody-coated cell by phagocytosis.	Autoimmune hemolytic anemia Blood transfusion reactions Rh hemolytic disease Some types of glomerulonephritis
III: Immune complex disease	Circulating antigen-antibody complexes form, which activate complement and cause inflammatory reaction.	Some types of glomerulonephritis Systemic lupus erythematosus Rheumatoid arthritis
IV: Delayed (cell-mediated) hypersensitivity	Sensitized (delayed hypersensitivity) T cells release lymphokines that attract macrophages and other inflammatory cells.	Tuberculosis Fungus and parasitic infections Contact dermatitis

FIGURE 8-19 Type I allergic reaction. The antigen stimulates the production of massive amounts of immunoglobulin E (IgE), a type of antibody produced by plasma cells; the IgE, in turn, attaches to mast cells. This is a sensitization stage. When the antigen enters again, it binds to the IgE antibodies on the mast cells, triggering a massive release of histamine and other chemicals. Histamine causes blood vessels to dilate and become leaky, and it promotes increased production of mucus in the respiratory tract. Mast cell degranulation may also cause bronchospasm in some people.

© Jones & Bartlett Learning.

Type II: Cytotoxic Hypersensitivity

Type II hypersensitivity reactions are cytotoxic (cell destructive) and classically involve the combination of immunoglobulin G (IgG) or immunoglobulin M (IgM) antibodies with antigens on the cell membrane. Cells are lysed (destroyed) by complement fixation or by other antibodies. This process also destroys many of the body's healthy cells. Histamine release from mast cells is not involved, and IgG-mediated allergic responses occur within a few hours of antigen exposure. Examples of IgG-mediated responses include transfusion reactions and newborn hemolytic disease.

Type III: Tissue Injury Caused by Immune Complexes

Type III hypersensitivity responses involve primarily IgG antibodies that form immune complexes with antigen to recruit phagocytic cells, such as neutrophils, to a site where they can release inflammatory cytokines. Because histamine release from mast cells is not involved, IgG-mediated allergic responses occur within a few hours of antigen exposure. Reactions may be systemic or localized.

The systemic form is called **serum sickness** and results from a large, single exposure to an antigen, such as horse antibody serum. Antigen-antibody complexes formed in the bloodstream are then deposited in sites around the body, most notably in the kidney, with resultant inflammatory reactions (such as serum sickness from penicillin). Signs and symptoms of serum sickness may include fever, malaise, rashes, joint aches, lymphadenopathy, and splenomegaly.

The localized form of a type III response is called an Arthus reaction. Arthus reactions consist of a circumscribed area of vascular inflammation (**vasculitis**). An example of an Arthus reaction is farmer's lung (a type of hypersensitivity pneumonitis reaction in the lung caused by inhalation of moldy hay dust).

Type IV: Delayed (Cell-Mediated) Hypersensitivity

Type IV allergic responses, also known as cell-mediated hypersensitivity, are primarily mediated by soluble molecules that are released by specifically activated T cells. These reactions are classified

into two subtypes: delayed hypersensitivity and cell-mediated cytotoxicity.

Delayed hypersensitivity involves lymphocytes and macrophages. T cells respond to an antigen and activate CD4 (a helper T cell) lymphocytes. These lymphocytes release mediators that are designed to destroy the foreign substance. An example is contact hypersensitivity to poison ivy.

Cell-mediated cytotoxicity involves only sensitized T cells (CD8 lymphocytes or **killer T cells**). These cells kill the antigen-bearing target cells rather than activating the CD4 lymphocyte to do so. Examples include the body's response to viral infections, tumor immune surveillance, and the mechanism by which transplant rejection occurs.

Targets of Hypersensitivity Reactions

The immune system targets different molecules, depending on the type of hypersensitivity reaction. In allergic reactions, the target is an antigen or allergen. Allergens are substances that cause a hypersensitivity reaction, such as those listed in **TABLE 8-7**.

Autoimmune Reactions

In autoimmune reactions, the target is a person's own tissues. For reasons that are unclear, normal tolerance of "self" tissues breaks down and the immune system treats the body's own tissues as foreign.

TABLE 8-7 Allergens That Can Cause Hypersensitivity Reactions

Type	Examples
Inhalants	Pollen, dust, smoke, fungi, plastic, odors
Food	Eggs, dairy, wheat, chocolate, strawberries
Drugs	Aspirin, antibiotics, serums, codeine
Infectious agents	Bacteria, viruses, fungi, animal parasites
Contactants	Animals, plants, metals, chemicals
Physical agents	Light, pressure, radiation, heat and cold

© Jones & Bartlett Learning.

Graves disease is an autoimmune disease caused by thyroid-stimulating or thyroid-growth immunoglobulins. These antibodies activate receptors for thyroid-stimulating hormone, causing increased activity by the thyroid gland. In addition to hyperthyroidism, Graves disease is associated with characteristic eye changes (lid retraction, stare, and exophthalmos [protrusion of the eyes]) and skin changes (pretibial myxedema—localized edematous skin in the pretibial area).

Type 1 diabetes mellitus is also considered an autoimmune disease. Although the exact insult is unknown (one possible suspect is a viral infection), some agent stimulates the body to produce autoantibodies against beta cells in the pancreas that produce insulin. The results are a deficiency of insulin and, therefore, diabetes.

Rheumatoid arthritis is a chronic systemic disease that affects the entire body. One of the most common forms of arthritis, it is characterized by inflammation of the synovium (the connective tissue membrane lining the joint) with resulting pain, stiffness, warmth, redness, and swelling. Inflammatory cells release enzymes that cause damage to bone and cartilage. The involved joint can lose its shape and alignment, resulting in pain and loss of movement. Rheumatoid arthritis is associated with the formation of rheumatoid factor—that is, IgM antibodies to tissue IgG. In the joints, the synovial membrane is thickened due to infiltration of inflammatory cells (lymphocytes).

Myasthenia gravis is an acquired autoimmune disease that is characterized by autoimmune attack on the nerve-muscle junction. The circulating autoantibodies cause abnormal muscle fatigability and typically involve the smallest motor units first, such as the extraocular muscles. This produces ptosis (droopy eyelid) and diplopia (double vision). Other muscles may be involved, causing problems with swallowing (dysphagia). Characteristically, repeated contraction of the affected muscles makes the symptoms worse. Two-thirds of people with myasthenia gravis have thymic abnormalities, with the most common being thymic hyperplasia. A few of those affected have a tumor of the thymus, called a thymoma.

SLE is a chronic autoimmune disease with many manifestations. In SLE, the body's immune system is directed against the body's tissues. The cause of SLE is not known. Although SLE is more

common in young women, it can occur in either sex at any age. The production of autoantibodies leads to immune complex formation. These immune complexes can then be deposited in glomeruli, skin, lungs, synovium, and mesothelium, among other places. Symptoms include arthritis, a red rash over the nose and cheeks, fatigue, weakness, fever, and photosensitivity. Glomerulonephritis (kidney disease), pericarditis, anemia, and neuritis may develop. In addition, many people with SLE have renal complications.

Immune Deficiencies

Immunodeficiency is an abnormal condition in which some part of the body's immune system is inadequate, and, consequently, resistance to infectious diseases is decreased. It may be congenital or acquired.

Congenital Immunodeficiencies

Patients with severe combined immunodeficiency disease have defects that involve lymphoid stem cells. Consequently, T cells (cellular immunity) and B cells (humoral immunity) are affected. Patients are at risk for infection with all types of organisms (bacteria, mycobacteria, fungi, viruses, parasites,

and prions). There are two forms of this disease, both of which are inherited.

Acquired Immunodeficiencies

Any nutritional deficiency can hamper normal immune function and the inflammatory response. Nutritional deficiencies may depress bone marrow function and diminish white blood cell development. A lack of protein in the diet, for example, decreases the liver's ability to manufacture inflammatory mediators and plasma proteins.

The stress of trauma can also cause immunodeficiency. Other contributors to this condition may include hypoperfusion or shock, mediator production, damage to vital organs, and the decreased nutrition occurring during trauma states.

Iatrogenic (treatment-induced) immunodeficiency is most often caused by medications. For example, corticosteroids, whether taken orally or inhaled, suppress the immune system. This immune system suppression often has therapeutic benefits. However, in a few patients, the immunosuppression in the context of exposure to a pathogen leads to other diseases, such as tuberculosis. Because of its potential for adverse effects, physicians are usually cautious about prescribing this therapy for a prolonged period. In addition, idiosyncratic reactions

YOU are the Provider

Part 4

Your partner reports all of the medication bottles are out of date and empty. You ask the patient about this and he states he does not have the means necessary to buy the medications. When you look at the list of medications, you find one for a diuretic. You note that the patient is tachycardic. The ETCO_2 waveform appears appropriate in shape and reads 36 mm Hg.

Recording Time: 7 Minutes

Respirations	24 breaths/min; shallow
Pulse	114 beats/min
Skin	Cool, pale, and moist
Blood pressure	138/88 mm Hg
Oxygen saturation (SpO_2)	92% with high-flow oxygen administration
Pupils	PERRLA

7. Why would a diuretic be prescribed for a patient with heart failure?
8. Why would this patient have a normal or slightly high blood pressure?

to antibiotics may cause bone marrow suppression. Bone marrow suppression in patients with cancer is often a direct side effect of chemotherapy and not a true idiosyncratic reaction.

Physical or mental stress has been shown to decrease white blood cell and lymphocyte function. It may also lead to decreased production of various antibodies.

AIDS is an immunodeficiency disease that is caused by the RNA retrovirus HIV. HIV binds to the CD4 surface protein of helper T cells, infects these cells, and kills them. The destruction of the cells causes decreased humoral and cell-mediated reactions.

Treatment of Immunodeficiencies

Replacement therapy is available for immunodeficiencies such as common variable immunodeficiency. IV gamma globulin has been used in the treatment of several immunologic disorders of the nervous system, especially myasthenia gravis and inflammatory neuropathies, with considerable success. Bone marrow transplantation may restore immune competence in patients with acquired causes of immunodeficiency, such as following chemotherapy to treat cancer. Transfusion is another form of replacement therapy for immunodeficiencies. In the future, gene therapy may be useful to treat congenital and acquired causes of immunodeficiency.

Factors That Cause Disease

Genetic, environmental, age-related, and sex-associated factors can cause or contribute to disease. Genetic factors are present at birth and are passed on through a person's genes to future generations. Environmental factors include microorganisms, immunologic vulnerabilities, personal habits and lifestyle, exposure to chemicals and other toxins, the physical environment, and the psychosocial environment. Family violence, for example, might be a key factor in causing depression or substance abuse, perhaps even years later. A sedentary lifestyle and a high-fat diet can cause or contribute to obesity, diabetes, heart disease, stroke, and other diseases.

Disease also can have anatomic causes. For example, malrotation of the colon is a disease in which the colon does not form properly, resulting in partial blockage. Another example is degenerative

diseases of the spine; as intervertebral disks age, they may degenerate to the extent that the patient experiences pain due to nerve compression. *Aortic stenosis* is a condition in which the aortic valve becomes very tight and narrowed, resulting in chest pain from decreased perfusion of the coronary arteries or heart failure.

Finally, an immunologic reaction may result in disease. An example is exposure to an agent that triggers an abnormal immune response against myelin, leading to the development of multiple sclerosis.

Controllable Versus Uncontrollable Risk Factors

Some uncontrollable factors, such as genetics and race, influence the development of disease, but many other factors can be controlled. For example, behaviors such as smoking, drinking alcohol, inadequate nutrition (excessive fat, salt, and sugar intake or insufficient intake of protein, fruits, vegetables, and fiber), lack of physical activity, and stress can be modified.

Age-Related Risk

The risk of a particular disease often depends on a person's age. For example, newborns are at greater risk of certain diseases because their immune systems are not fully developed. Teenagers are at high risk of injury resulting from trauma and illicit drug and alcohol use. As people get older, the risk of having cancer, heart disease, stroke, and Alzheimer disease increases. See Chapter 35, *Obstetric and Neonatal Care*; Chapter 36, *Pediatric Emergencies*; and Chapter 37, *Geriatric Emergencies* for additional information on specific age-related conditions.

Sex-Associated Factors

In some cases, sex is related to the risk of having a certain disease. Note: A person's physical sex and gender are not necessarily aligned. In this discussion, we are referring to a person's genetic sex; for example, a person born with an XY sex chromosome is genetically and physically male, even if the person's gender is female.

Some diseases present differently in women compared with men (such as in the presentation of AMI). For example, the hormones found in a premenopausal woman have been shown to have

protective benefits in major head trauma and certain cardiac conditions.

Finally, genetic disorders are related to a person's sex when a defective gene is located on a sex chromosome. Most sex-linked disorders are X linked. X-linked disorders may be either recessive or dominant. Because females have two X chromosomes, those with a defective X gene may not have the disorder; if the disorder is recessive, the X chromosome without the defect will mask the defective X chromosome. Men with a defective X gene will always be affected because they only have one X chromosome; the defect cannot be masked.

Analysis of Disease Risk

Analyzing disease risk involves consideration of disease rates and disease risk factors (causal and noncausal). Risk factors that can directly cause a disease to develop are called causal risk factors. For example, *Mycobacterium tuberculosis* is a causal risk factor for a person becoming infected with tuberculosis. Risk factors that are associated with risk for a disease but not a direct cause are called noncausal risk factors. Poverty is a noncausal risk factor for tuberculosis.

All studies of a disease should consider the incidence, prevalence, and mortality of the disease. The **incidence** is the number of new cases of a disease in a population in a given time period (for example, six new cases of West Nile virus infection developed in the county last year). **Prevalence** refers to the total number of cases of a disease or condition in a specific population within a particular period (for example, last year, more than 100,000 patients in the country had this disease). **Morbidity** refers to the damage or suffering caused by the disease either in an individual patient or in the population as a whole. **Mortality** is most often discussed as the mortality rate, which is the number of deaths from a disease in a given population, expressed as a proportion (for example, 1 in 50 affected people in the United States will die from the disease). **TABLE 8-8** illustrates how the concepts of incidence, prevalence, morbidity, and mortality might be expressed, using statistics on diabetes as an example.

Interaction of Risk Factors

Risk factors, age, and sex differences often interact. For example, suppose a person has a genetic

TABLE 8-8 Incidence, Prevalence, Morbidity, and Mortality Rate of Diabetes in the United States

Term	Example
Incidence	Every year, 1.5 million Americans are newly diagnosed with type 1 or type 2 diabetes. In 2015, an additional 88 million Americans age 18 years and older were newly categorized as prediabetic.
Prevalence	In 2018, 10.5% of the total US population (adults and children) had diabetes.
Mortality rate	In 2017, diabetes was responsible for or a key contributor to the deaths of 270,702 people.
Financial cost	In 2017, Americans spent \$237 billion treating diagnosed diabetes, and the disease cost the US economy another \$90 billion in reduced productivity.

Data from Centers for Disease Control and Prevention. *National Diabetes Statistics Report: Estimates of Diabetes and Its Burden in the United States, 2014*. Atlanta, GA: U.S. Department of Health and Human Services; 2014. www.cdc.gov/diabetes/pubs/statsreport14/national-diabetes-report-web.pdf. Accessed January 6, 2017; and American Diabetes Association. *Statistics About Diabetes*. www.diabetes.org/diabetes-basics/statistics/. Accessed January 6, 2017.

tendency toward coronary artery disease; the risk of myocardial infarction or sudden death is higher in this person even if he or she exercises regularly and has no other risk factors. A person who smokes heavily but has no other risk factors may have a similarly elevated risk. **TABLE 8-9** shows the interplay of various risk factors in causing respiratory disease.

Common Familial Diseases and Associated Risk Factors

The terms *genetic risk* and *familial tendency* are often used interchangeably. A true genetic risk is one that is passed through generations by inheritance of a gene. In contrast, diseases with a familial tendency seem to cluster in family groups despite lack of evidence for heritable gene-associated abnormalities.

Immunologic Disorders

Immunologic diseases are caused by hyperactivity or hypoactivity of the immune system. Most immunologic diseases that exhibit familial tendencies

TABLE 8-9 Common Respiratory Diseases

Disease	Pathology and/or Symptoms	Causes and Possible Contributing Causes
Emphysema	Breakdown of alveoli, shortness of breath	Smoking Air pollution Possible genetic susceptibility Exacerbated by obesity
Chronic bronchitis	Cough, shortness of breath	Smoking Air pollution Possible genetic susceptibility Exacerbated by obesity
Acute bronchitis	Inflammation of the bronchi; coughing up yellow mucus; shortness of breath	Many viruses and bacteria Possible genetic susceptibility Smoking Exacerbated by obesity
Sinusitis	Inflammation of the sinuses; characterized by mucus discharge, blocked nasal passages, and headache	Many viruses and bacteria Poor general health
Laryngitis	Inflammation of larynx and vocal cords, sore throat, hoarseness, mucus buildup, and cough	Many viruses and bacteria Poor general health
Pneumonia	Inflammation of the lungs, ranging from mild to severe; cough and fever, shortness of breath at rest, chills, sweating, chest pain, blood-tinged mucus	Bacteria, viruses, fungi, or inhalation of irritating gases Lack of physical activity
Asthma	Constriction of bronchioles, mucus buildup in bronchioles, periodic wheezing, difficulty breathing	Allergy to pollen, certain foods, food additives; dander (dead skin cells and other debris shed by dogs, cats, or birds) Physical activity (exercise-induced asthma) Probable genetic link

© Jones & Bartlett Learning.

involve an overactive immune system—for example, allergies, asthma, and rheumatic fever. Substantial overlap exists often among causative factors, including the person's environment.

Allergies are acquired following initial exposure to an allergen. Repeated exposures cause the immune system to react to the allergen (**FIGURE 8-20**). Although the clinical presentation varies, it usually includes swelling and itching, runny nose, coughing, sneezing, wheezing, and nasal congestion. A person who has an allergic tendency is said to be **atopic**. Environmental conditions may also increase a person's susceptibility to an allergic reaction.

Asthma is a chronic inflammatory condition of the lower airway resulting in intermittent wheezing and excess mucus production. Nearly 60% of attacks are precipitated by viral infections. Allergies

Special Populations

Rheumatic fever is an inflammatory disease that occurs primarily in children. This disease results from a delayed reaction to an untreated streptococcal infection of the upper respiratory tract (such as strep throat). Symptoms, which appear several weeks after the acute infection, may include fever, abdominal pain, vomiting, arthritis, palpitations, and chest pain. Recurrent episodes of rheumatic fever may cause permanent myocardial damage, especially to the cardiac valves. A family history of acute rheumatic fever may predispose a person to the disease.

account for another 20% of asthma attacks, with stress and emotions causing the remainder. In addition to the familial component, chromosomal

FIGURE 8-20 Pathogenesis of allergy. First, exposure to an allergen induces formation of specific immunoglobulin E (IgE) antibodies in susceptible patients, which then bind to mast cells and basophils. Subsequent exposure to the same allergen leads to antigen-antibody interaction through activation of memory cells, liberating histamine and other mediators from mast cells and basophils. These mediators induce allergic manifestations.

© Jones & Bartlett Learning.

differences in certain patients may enhance their susceptibility to asthma.

Cancer

Cancer describes the pathology associated with malignant growths (neoplasms) in various anatomic areas of the human body. The prognosis often depends on the extent of its spread (metastasis) and the effectiveness of treatment.

A major risk factor associated with lung cancer is cigarette smoking. Research has identified eight alterations in the genetic material of lung cancers that suggest a genetic tendency to develop the disease. Other predisposing factors include exposure

to asbestos, coal products, and other industrial and chemical products. Symptoms include cough, difficulty breathing, blood-tinged sputum, and repeated infections. Treatment depends on the type, site, and extent of the cancer and may include surgery, chemotherapy, and/or radiotherapy.

Breast cancer is the most common type of cancer occurring among women and accounts for as many as 276,480 newly diagnosed cases and 42,170 deaths each year in the United States.¹¹ Women whose first-degree relatives (such as a parent, sister, or daughter) have breast cancer are 2.1 times more likely to have the disease. Risk varies with the age at which the affected relative was diagnosed;

A

B

FIGURE 8-21 Breast carcinoma. **A.** Cross section of breast biopsy specimen. The tumor appears as a firm mass with poorly defined edges that infiltrate the surrounding fatty breast tissue. **B.** Appearance of breast carcinoma in a mammogram. The tumor appears as a white area with infiltrating margins.

Courtesy of Leonard V. Crowley, MD, Century College.

the younger the age at occurrence, the greater the risk posed to relatives. The susceptibility may be inherited through the mother's or the father's side of the family.

Early symptoms of breast cancer are usually detected by the woman during breast self-examination and include a small, painless lump; thick or dimpled skin; or a change in the nipple (**FIGURE 8-21**). Later symptoms include nipple discharge, pain, and swollen lymph glands in the axilla. Treatment depends on the location, size, and metastasis of the tumor.

Colorectal cancer is the third most common type of cancer in men and women. In 2020, the American Cancer Society expected 147,950 new cases and an estimated 53,200 deaths from colorectal cancer in the United States.¹¹ Relatives of people diagnosed with colorectal cancer are more likely to have the

disease themselves, and parents can pass on to their children changes in certain genes that can lead to colorectal cancer. Symptoms may be minimal, consisting only of small amounts of blood in the stool. Treatment involves surgery and sometimes chemotherapy. Periodic rectal examinations and colonoscopy are recommended for adults age 50 years and older to detect the disease at an early stage.

Endocrine Disorders

Diabetes mellitus is one of the most significant endocrine diseases. This chronic disorder of metabolism is associated with partial insulin secretion or total lack of insulin secretion by the pancreas, which in turn affects the body's ability to use glucose. Symptoms include excessive thirst and urination, weight abnormalities, and the presence of excessive glucose in the urine and the blood.

Ketoacidosis-prone (type 1) diabetes is also known as insulin-dependent diabetes mellitus because patients need exogenous insulin to survive. Non-ketoacidosis-prone (type 2) diabetes is called non-insulin-dependent diabetes, even though many people with type 2 diabetes require exogenous insulin injections. Both forms have a hereditary predisposition. Type 1 diabetes has no known cure (other than pancreas transplantation) at the present time; type 2 diabetes can occasionally be brought under control with weight loss, regular physical activity, and medications.

Hematologic Disorders

Hemolytic anemia is characterized by increased destruction of red blood cells. This disorder has a number of causes, such as an Rh factor blood transfusion reaction (which would most likely occur in the neonate population), a disorder of the immune system, and exposure to bacterial toxins or chemicals such as benzene. **FIGURE 8-22** depicts how the body handles iron. Hemolytic anemia following an aspirin overdose or penicillin administration is rare; it is much more common, albeit still rare, with sulfa drugs used to treat urinary tract infections, such as the trimethoprim-sulfamethoxazole combination (known as Septra and Bactrim). An inherited enzyme deficiency (glucose-6-phosphate dehydrogenase deficiency) markedly increases a person's susceptibility to sulfa drug-induced hemolytic anemia.

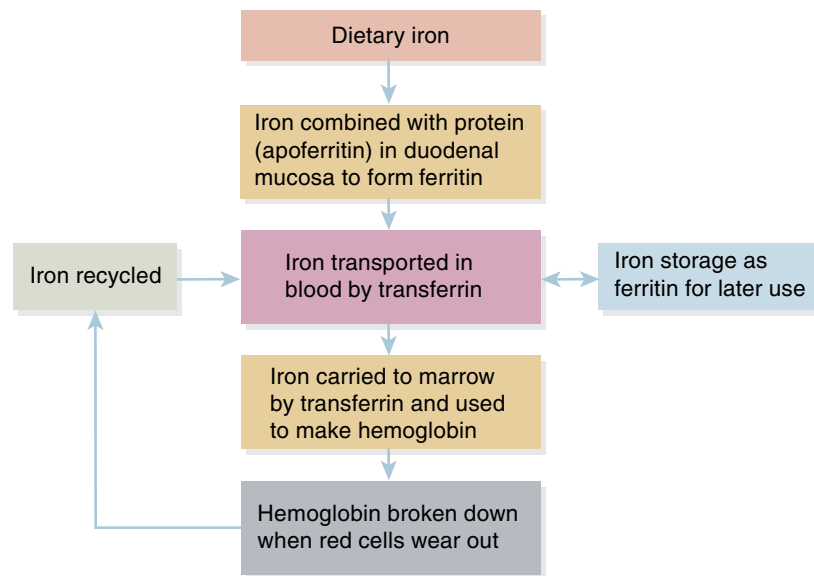

FIGURE 8-22 Iron uptake, transport, storage, and utilization for hemoglobin synthesis. Most of the iron used for hemoglobin synthesis is recycled from worn-out red blood cells. Chronic blood loss removes iron-containing cells from the circulation, and the iron contained in the red blood cells can no longer be recycled to make hemoglobin, leading to iron-deficiency anemia.

© Jones & Bartlett Learning.

Hemophilia is an inherited disorder characterized by excessive bleeding. It is a sex-linked condition, occurring predominantly in males, and is passed from asymptomatic mothers to sons.¹² In this disorder, one of the blood-clotting proteins (usually factor VIII) necessary for normal blood coagulation is missing or is present in abnormally low amounts. Patients experience greater-than-usual blood loss in dental extractions and following simple injuries. They may also have bleeding into joints and, rarely, into the brain. Treatment consists of administration of the missing blood-clotting factors.

Hemochromatosis is an inherited disease in which the body absorbs more iron than it needs. The excess iron is stored in various organs, including the liver, kidneys, and pancreas. Hemochromatosis can lead to diabetes, heart disease, liver disease, arthritis, impotence, and a bronzed skin color. These symptoms can be avoided by regularly drawing blood (phlebotomy).

Cardiovascular Disorders

Several cardiovascular disorders are known to follow specific patterns of inheritance. Still others have strong familial tendencies (such as coronary heart disease).

Cardiomyopathy

Cardiomyopathy is a general term for diseases of the myocardium (heart muscle) that ultimately progress to heart failure, AMI, or death. These diseases cause the heart muscle to become thin, flabby, dilated, or enlarged. One variant, hypertrophic cardiomyopathy, is genetically predisposed for inheritance in each generation. The main feature of hypertrophic cardiomyopathy is an excessive thickening of the heart muscle (hypertrophy means to thicken or grow excessively) (**FIGURE 8-23**). In addition, microscopic examination of the heart muscle shows that it is abnormal. Patients may have shortness of breath, chest pains, palpitations, or syncope; sudden cardiac death is also possible. Beta-blockers are effective treatment in some patients. Others require surgery or an automatic implantable cardiac defibrillator designed to deliver a shock to the heart.

Mitral Valve Prolapse

Also referred to as a floppy mitral valve, mitral valve prolapse (MVP) is relatively common, affecting nearly 3% of the US population.¹³ A familial tendency toward MVP exists, but the condition is usually associated with other cardiovascular conditions.

FIGURE 8-23 Comparison of normal cardiac function with malfunction characteristic of hypertrophic cardiomyopathy. **A.** Normal heart, illustrating unobstructed flow of blood from left ventricle into aorta during ventricular systole. **B.** Hypertrophic cardiomyopathy, illustrating obstruction to outflow of blood from left ventricle by hypertrophied septum, which impinges on the anterior leaflet of mitral valve.

© Jones & Bartlett Learning.

The mitral valve leaflets balloon into the left atrium during systole. Although MVP is often benign and asymptomatic, some patients have chest pain, fatigue, dizziness, dyspnea, or palpitations. Generally, the only physical finding is a clicking sound heard during cardiac auscultation. Cardiac dysrhythmias develop in a small number of patients.

Sometimes MVP leads to mitral regurgitation (also called mitral insufficiency), in which a large amount of blood leaks backward through the defective valve. Mitral regurgitation can lead to thickening or enlargement of the heart wall, caused by the extra pumping of the heart to make up for the back-flow of blood. It sometimes causes people to feel tired or short of breath. Mitral regurgitation usually can be treated with medication, but some people need surgery to repair or replace the defective valve.

Coronary Heart Disease

Coronary heart disease, often called coronary artery disease, is caused by impaired circulation to the heart. Typically, patients have occluded coronary arteries from atherosclerotic plaque buildup. The effects can range from ischemia to infarction and necrosis (death) of the myocardium. Coronary artery disease is the leading cause of death in the

United States.¹⁴ This condition has a familial tendency; significant risk factors for coronary artery disease development include having a father who experienced an AMI or died suddenly younger than 55 years of age or having a mother who experienced an AMI or died suddenly younger than 65 years of age. Other risk factors include hypercholesterolemia, cigarette smoking, hypertension (high blood pressure), age (as age increases, the risk for coronary heart disease increases), and diabetes.

Hypercholesterolemia is an elevation of the blood cholesterol level. The blood cholesterol level is divided into high-density lipoprotein (“good cholesterol”) and low-density lipoprotein (“bad cholesterol”). Despite having a normal total cholesterol level, having an abnormally low level of high-density lipoprotein and/or an elevation of low-density lipoprotein increases the risk of coronary heart disease.

Hypertension and Stroke

Hypertension (high blood pressure) is associated with an increased risk of coronary artery disease and is also strongly associated with an increased risk of stroke. Risk factors for developing hypertension can be categorized as genetic or lifestyle-related and include age (as age increases, the risk increases), race

(more common in African Americans), sex (men are more likely to experience hypertension), family history, obesity or being overweight, sedentary lifestyle, tobacco use, diet (too much salt, too little potassium, too little vitamin D, too much alcohol), and stress.

Stroke risk factors are also either genetic or lifestyle-related and include age (adults 55 years or older are at increased risk), race (more common in African Americans, Hispanics, and American Indian/Alaska Natives), sex (men are more likely to have a stroke), family history, obesity or being overweight, sedentary lifestyle, hypertension, hypercholesterolemia, tobacco use, diabetes, cardiovascular disease, using birth control pills or hormone therapies, and excessive alcohol consumption.

Renal Disorders

Gout

Gout is an abnormal accumulation of uric acid due to a defect in metabolism. As a result of this defect, uric acid accumulates in the blood and joints, causing pain and swelling of the joints, especially the big toe. Often, the patient has fever and chills. Gout is more common among men than women and usually has a genetic basis. If left untreated, gout causes destructive tissue changes in the joints and kidneys. Treatment includes diet and medications to reduce inflammation and to increase the excretion of uric acid or decrease its formation.

Kidney Stones

Kidney stones are small masses of uric acid or calcium salts that form in any part of the urinary system (kidney, ureter, or urinary bladder). Kidney stones may cause severe pain, nausea, and vomiting when the body attempts to pass them. Although most stones are small, occasionally they become large enough to adopt the internal contours of the kidney (**FIGURE 8-24**). Researchers have found a gene that causes the intestines to absorb too much calcium, which can lead to the formation of kidney stones. Uric acid stones also often have a genetic basis. Some are small enough to pass in the urine, with or without pain; others must be removed surgically.

Gastrointestinal Disorders

Malabsorption Disorders

Malabsorption disorders are caused by defects in the function of the bowel wall that prevent

FIGURE 8-24 Large staghorn-shaped kidney stone.

Courtesy of Leonard V. Crowley, MD, Century College.

adequate nutrient absorption. The result is a complex of symptoms, including loss of appetite, bloating, weight loss, muscle pain, and stools with high fat content. Diarrhea, which may be bloody, may also be a prominent symptom.

Lactose intolerance is caused by a defect or deficiency of the enzyme lactase, resulting in an inability to digest lactose (milk sugar). Symptoms include bloating, flatulence, abdominal discomfort, nausea, and diarrhea after ingesting dairy or dairy products.

Ulcerative colitis is a serious chronic inflammatory disease of the large intestine and rectum. This disease, which shows a familial tendency, is characterized by recurrent episodes of abdominal pain, fever, chills, and profuse diarrhea, with stools containing pus, blood, and mucus. Treatment consists of anti-inflammatory agents, including corticosteroids. Patients with severe cases may require surgery to remove parts of the intestinal tract. Patients are at increased risk for the development of colorectal cancer.

Crohn disease is a serious chronic inflammatory condition affecting the colon and/or the terminal portion of the small intestine. It is believed to

be associated with as-yet-undetermined gene abnormalities. Symptoms include frequent episodes of diarrhea, melena, abdominal pain, nausea, fever, weakness, and weight loss. Management is by anti-inflammatory agents, antibiotics, proper nutrition, and sometimes surgery to remove the damaged portion of the bowel, fistulas, or scar tissue.

Peptic Ulcer Disease

Peptic ulcer disease is characterized by circumscribed erosions (ulcerations) of the mucous membrane lining of the gastrointestinal tract—specifically, in the esophagus, stomach, duodenum, or jejunum. Peptic ulcers may be associated with excess acid production or a breakdown in the normal mechanisms protecting the mucous membranes. Although this disease seems to have a genetic component, a major contributor to its development is infection with the bacterium *Helicobacter pylori*—the observed familial patterns seem to be due to shared infections with *H. pylori*. Symptoms include gnawing pain, which is often worse when the stomach is empty, after the person eats certain foods, or when the person is under stress. Treatment includes avoiding irritants such as tobacco, alcohol, and certain foods, antibiotics, and medications to decrease acidity. In refractory cases, surgery may be necessary.

Callstones

Gallstones (choleliths) are stonelike masses in the gallbladder or its ducts caused by precipitation of substances contained in bile (such as cholesterol and bilirubin). Factors that contribute to the formation of gallstones include abnormalities in the composition of bile, or stasis of bile. Gallstones may be asymptomatic, but they cause symptoms when they obstruct the flow of bile. They may cause inflammation of the gallbladder. Small stones that are able to pass into the common duct produce indigestion and biliary colic. Biliary colic pain has a sudden onset and increases steadily to its maximum in approximately 1 hour. The pain is located in the upper right quadrant or the epigastric area and may be referred to the back. Larger stones may cause jaundice (yellow skin and sclerae).

Obesity

Obesity is an unhealthy accumulation of body fat and is defined as a body mass index of greater than

or equal to 30 kg/m^2 . For example, an adult who is 5 feet 9 inches tall (2 m) and who weighs more than 203 pounds (92 kg) is considered obese. Body mass index, and therefore the definition of obesity, is different for children and adolescents.

Morbid obesity is defined as a body mass index of 40 kg/m^2 or greater. Using the example again of adults who are 5 feet 9 inches tall (2 m), they are considered morbidly obese if they weigh more than 270 pounds (122 kg). Morbid obesity includes all health risks associated with obesity, but it also makes basic functions such as walking or breathing difficult.

People who are overweight are also at increased risk for disease, although the risk is not as high as for those who are obese. Being **overweight** is defined as a body mass index of 25 to 29.9 kg/m^2 . Using the previous example of an adult who is 5 feet 9 inches tall (2 m), he or she would be overweight if he or she weighed between 169 and 202 pounds (77 and 92 kg).

Obesity has a substantial negative impact on a person's health and life span; simply put, it has been statistically proven that the life span of a person with obesity is decreased by an average of 8 to 13 years.^{15,16} Obesity has become an epidemic among adults and children in the United States. Approximately two-thirds of adults in the United States are obese or are overweight. Approximately 30% of children and adolescents in the United States are obese.^{15,16}

Obesity has many deleterious effects, both medical and social. Health risks associated with obesity include hypertension, hyperlipidemia, cardiovascular disease, glucose intolerance, insulin resistance, diabetes, gallbladder disease, infertility, and cancer of the endometrium, breast, prostate, and colon. Social and psychological effects of obesity include depression, anxiety, shame, rejection, and discrimination in various environments, including school and the workplace.

Although some people likely have a genetic predisposition to obesity, the roles of specific genes in its development have yet to be determined. Behavioral and environmental factors are better known. Behavioral factors that contribute to obesity include choosing a sedentary lifestyle, overeating, or eating foods high in calories and low in nutritional value, such as fast food and soda. A person's community or work environment may make it difficult to choose to be physically active or to eat properly. For

example, a lack of sidewalks in a community would contribute to the risk of members of that community becoming obese. Large portion sizes offered by restaurants contribute to a lack of understanding of proper portion size. Finally, interest in television and technological media may take time away from physical activity and encourage unhealthy product consumption. Because people tend to snack while watching TV or using a computer, they consume unnecessary additional calories.

Words of Wisdom

Although not a new concept, food deserts became more prevalent across the United States with the continuing COVID-19 pandemic in 2020. The term refers to an area where it is difficult to find affordable or nutritious food, a condition often seen in urban areas. During the pandemic, many food processing plants closed due to outbreaks of the virus. This lack of food processing trickled down to consumers, leaving shelves empty and customers scrambling from store to store to find the basics. Many small businesses also closed permanently, shut down initially as a result of mandatory closings to halt the spread of the virus but financially unable to continue once restrictions were lifted. These closings further expanded the distance to sources of nutritious food for those living in food deserts.

Neuromuscular Disorders

Although environmental contributions are highly likely, certain neuromuscular disorders have a familial and genetic basis. The next few sections present several of the better known and more worrisome disorders in this category.

Huntington Disease

Huntington disease (also called Huntington chorea) is a hereditary condition characterized by progressive chorea (involuntary rapid, jerky motions) and mental deterioration, leading to dementia. Symptoms usually first appear in the third or fourth decade of life and progress to death, often within 15 years.

Muscular Dystrophy

Muscular dystrophy is a generic term for a group of hereditary diseases of the muscular system characterized by weakness and wasting of groups

of skeletal muscles, leading to increasing disability. The various forms differ in age of onset, rate of progression, and mode of genetic transmission. Duchenne muscular dystrophy is a sex-linked recessive disease (affecting only males); symptoms first appear around 4 years of age. Progressive wasting of leg and pelvic muscles produces a waddling gait and abnormal curvature of the spine. Usually, by age 12, the person becomes unable to walk and begins to use a wheelchair. No known treatment exists, and most patients die, typically of a heart disorder, by age 20 years.

Multiple Sclerosis

Multiple sclerosis is a progressive disease in which the myelin sheath surrounding the nerve fibers of the brain and spinal cord become damaged.¹⁷ Although the disease is not directly inherited, some patients have a familial predisposition, suggesting a genetic influence on susceptibility. The disease usually begins in early adulthood and progresses slowly, with periods of remission and exacerbation. Early symptoms include abnormal sensations in the face or extremities, weakness, and visual disturbances (such as double vision), which progress to ataxia (lack of coordination), abnormal reflexes, tremors, difficulty in urination, and difficulty in walking. Depression is also common. No specific treatment or cure has been developed, but corticosteroids and other drugs are used to treat symptoms.

Special Populations

Never assume that new or worsening confusion in an older adult is due solely to Alzheimer disease without first considering potentially correctable causes such as new medications, infections, or myocardial infarction. An apparent emotional, psychological, or behavioral disorder may have an organic cause, especially in the older adult population.

Alzheimer Disease

Alzheimer disease is characterized by cortical atrophy and loss of neurons in the frontal and temporal lobes of the brain; in addition, as the brain ventricles become enlarged, a loss of brain tissue occurs. Alzheimer disease affects over 5 million Americans.¹⁸ Histologic changes in the brain of a person

A

B

FIGURE 8-25 Alzheimer disease. **A.** Thickened neurofilaments encircle and obscure the nuclei of nerve cells (arrow), forming a neurofibrillary tangle (magnification, $\times 400$). **B.** Three senile plaques (arrows) composed of broken masses of thickened neurofilaments (magnification, $\times 100$).

Courtesy of Leonard V. Crowley, MD, Century College.

with Alzheimer disease include neurofibrillary tangles and senile plaques (**FIGURE 8-25**). Studies of the genetics of inherited early-onset Alzheimer disease have been linked to mutations on three genes.

Alzheimer disease is progressive. Early in its progression, it is characterized by memory loss, lack of spontaneity, subtle personality changes, and disorientation to time and date. It may then progress to including impaired cognition and abstract thinking, restlessness and agitation, wandering, inability to perform activities of daily living, impaired judgment, and inappropriate social behavior. Advanced Alzheimer disease involves indifference to food, inability to communicate, urinary and fecal incontinence, and seizures.

Psychiatric Disorders

Some common psychiatric disorders seem to have a familial and perhaps even genetic component. Two of the most important are schizophrenia and bipolar disorder.

Schizophrenia

Schizophrenia comprises a group of mental disorders characterized by gross distortions of reality (psychoses); withdrawal from social contacts; and disturbances of thought, language, perception, and emotional response. Its symptoms are highly varied but may include apathy, catatonia or excessive activity, bizarre actions, hallucinations, delusions, and rambling speech. Although the cause of schizophrenia has not been identified, a combination of hereditary or genetic predisposing factors is likely in most cases.

Bipolar Disorder

Bipolar disorder (formerly known as manic-depressive disorder or manic-depressive psychosis) is a mental disorder characterized by episodes of mania and depression. One or the other phase may be dominant at any given time, the phases may alternate, or aspects of both phases may be present at once. The higher rates of bipolar disorder among relatives, identical twins, and biologic parents versus adoptive parents have been cited as evidence of the role of genetics in this disorder; the risk within the general population is approximately 2.6%.¹⁹ Treatment consists of psychotherapy plus certain atypical antipsychotics.

Stress and Disease

Stress is the medical term for a wide range of strong external stimuli, physiologic and psychological, that can cause a physiologic response. Physiologic stress is defined as a change that makes it necessary for the cells of the body to adapt. **FIGURE 8-26** shows the series of events that occur when the body responds to a stimulus or stressor. Three concepts related to physiologic stress include the stressor itself, its effect in the body, and the body's response to the stress.

The brain and CNS constantly interact with a person's consciousness. Research has shown a strong connection between the human psyche and

FIGURE 8-26 Physiologic response to stress.

© Jones & Bartlett Learning.

brain physiology. When a person experiences stress, the body's defense mechanisms are activated. Usually, the response to stress is appropriate and beneficial. However, an unchecked stress response can have deleterious outcomes, including chemical dependency, heart attack, stroke, depression, headache, and abdominal pain.

General Adaptation Syndrome

The **general adaptation syndrome**, a term introduced in the 1920s by Hans Selye, an Austrian endocrinologist, characterizes a three-stage reaction to stressors, physical (such as injury) and emotional (such as loss of a loved one).

Stage 1: Alarm

The body reacts to stress first by releasing catecholamines, chemical compounds derived from the amino acid tyrosine that act as hormones or neurotransmitters. They are produced mainly from the adrenal medulla and the postganglionic fibers of the sympathetic nervous system. Catecholamines are soluble, so they circulate dissolved in blood. The most abundant catecholamines are epinephrine (adrenaline), norepinephrine (noradrenaline), and

dopamine. Adrenaline acts as a neurotransmitter in the CNS and as a hormone in the blood. Noradrenaline is primarily a neurotransmitter of the peripheral sympathetic nervous system but is also present in the blood (mostly through spillover from the synapses of the sympathetic system).

As shown in Figure 8-26, stress causes the sympathetic nervous system to be stimulated. When the body senses stress, the brain causes the adrenal medulla of the endocrine system to send catecholamines (the hormones epinephrine and norepinephrine) that activate the sympathetic nervous system by binding to **receptor** sites. In the sympathetic nervous system, the receptors that allow certain responses to be activated are called alpha and beta receptors. When one of these receptors is activated, a predictable sequence of responses occurs. Activation of alpha receptors results in vasoconstriction, whereas activation of beta receptors results in increased heart rate, increased force of contraction, and increased conduction velocity. Beyond those cardiac effects of catecholamines, other physiologic effects include an increase in respiratory rate, decreased blood flow to the skin, smooth muscle constriction, and various effects on the liver that increase the body's use of glucose.

Normally, the fight-or-flight response that occurs in the alarm reaction prepares the body to deal with stress, but it can also weaken the immune system, leading to infection.

Stage 2: Resistance or Adaptation

During stage 2, the resistance or adaptation stage, the body adapts to stressors primarily by stimulating the adrenal gland to secrete two types of corticosteroid hormones that increase the blood glucose level and maintain blood pressure: glucocorticoids and mineralocorticoids. The most significant glucocorticoid in the body is cortisol, which controls carbohydrate, fat, and protein metabolism. Cortisol also has potent anti-inflammatory actions. Mineralocorticoids (predominantly aldosterone) control electrolyte and water levels in the body, mainly by promoting sodium retention by the kidneys.

During times of stress, the hypothalamus secretes a hormone that stimulates the anterior pituitary to release adrenocorticotrophic hormone (ACTH) (FIGURE 8-27). ACTH targets the adrenal cortex, resulting in cortisol secretion. Cortisol stimulates body cells to increase their energy production in response to increased stressors; cortisol increases serum glucose levels and impairs the use of glucose by peripheral tissues. It also decreases protein reserves and permits mobilization of fatty acids by epinephrine and growth hormone. It reduces inflammation when inflammation has served its purpose; therefore, it has a role in wound healing. Cortisol also increases red blood cell production and affects electrolyte levels. However, it also decreases the size of lymphoid tissue. Because the lymphatic system has an important role in immunity, this may explain why stress and disease are linked.

Other hormones related to stress include endorphins, which are neurotransmitters released during times of stress. Endorphins help reduce pain and stress by activating opiate receptor sites. They essentially produce a type of analgesia.

Additional hormones include growth factor, prolactin, and testosterone. Growth factor is a hormone that promotes cell and tissue growth and repair. In the context of stress, growth factor is reduced. Because growth factor correlates to the body's ability to heal, the body's ability to heal is reduced when it is under chronic stress.

Prolactin is a hormone that stimulates breast milk production. It is also believed to play a role

FIGURE 8-27 Stress triggers secretion of adrenocorticotrophic hormone, which results in cortisol secretion.

© Jones & Bartlett Learning.

in the immune system. In times of stress, prolactin levels increase. Research suggests that prolactin levels increase more in people with ineffective coping mechanisms.

The hormone testosterone is affected by stress. There is a direct link between cortisol levels and testosterone levels; namely, that when cortisol levels are high, testosterone levels are reduced. When the body is not under stress, testosterone levels are protected from cortisol by an enzyme. In the presence of stress, cortisol levels are too high for the enzyme to sufficiently handle them. As a result, the excess cortisol causes testosterone levels to decrease.

It was previously believed that elevated testosterone levels were linked to a suppressed immune system. Now, research suggests that testosterone may be related to the distribution of white blood cells in the body. It is thought that in times of stress, white blood cells are sent to the skin to protect against wound infection. But in the context of chronic stress, this would mean fewer white blood cells in other parts of the body on a regular basis, making those parts more susceptible to infection.

Cortisol levels and the sympathetic nervous system return to normal during this resistance or adaptation stage, causing fight-or-flight symptoms to disappear. Continuation of stress and accompanying corticosteroid release eventually lead to fatigue, lapses in concentration, irritability, lethargy, depression, and a depressed immune system.

Stage 3: Exhaustion

After a long period of stress, the person enters the exhaustion stage. The adrenal glands become depleted, decreasing the blood glucose level, which results in decreased stress tolerance, progressive mental and physical exhaustion, illness, and collapse. At this point, the body's immune system is compromised, substantially reducing a person's ability to resist disease. Heart attack, high blood pressure, or severe infection may result.

Effects of Chronic Stress

The **hypothalamic-pituitary-adrenal axis** is a major part of the neuroendocrine system that controls reactions to stress. The hypothalamic-pituitary-adrenal axis triggers a set of interactions among the glands, hormones, and parts of the midbrain that mediate the general adaptation syndrome. Continued stress, however, leads to loss of these normal control mechanisms. As a result, the adrenals

continue to produce cortisol, which exhausts the stress mechanism and leads to fatigue and depression. Cortisol also interferes with serotonin activity, furthering the depressive effect.

A consistently high cortisol level suppresses the immune system by increasing production of interleukin-6, an immune system messenger. Not surprisingly, then, research indicates that stress and depression have a negative effect on the immune system. Reduced immunity makes the body more susceptible to everything from colds and flu to cancer. For example, the incidence of serious illness, including cancer, is substantially higher among people whose spouse has died during the past year.

Although severe, prolonged stress does not cause death directly, it does cause the body to lose its ability to fight disease in its effort to manage the stress. Stress also encourages the body to release fat and cholesterol into the bloodstream, which then block the arteries and can eventually cause a heart attack or stroke. Many people start drinking alcohol to excess to combat their stress. Other diseases and conditions related to chronic stress include depression, headaches, insomnia, ulcers, diuresis, acne, diabetes mellitus, rheumatoid arthritis, and asthma. The variety in this list shows that stress affects most every organ system in the body.

However, it is important to note that a person's reaction to stressful events correlates to elevation or reduction in hormone levels. Therefore, coping mechanisms play a role in the physiologic response to stress. When a healthy person experiences stress, he or she may be able to manage the stress with minimal negative effects to the immune system if he or she has effective coping mechanisms. Ineffective coping mechanisms, however, will have deleterious effects on immune status in any patient. Effects will be worst in those whose immune systems are already compromised and who do not have effective coping mechanisms to combat the stress. Conversely, effective coping mechanisms can go a long way in helping a patient improve the immune system's response. Finally, a person's outlook has been shown to relate to the effectiveness of the medical treatment; much like a placebo effect, if a patient believes that the treatment will be effective, it is more likely to be effective.

YOU are the Provider SUMMARY**1. What is your general impression of the patient?**

The patient is in obvious respiratory distress because he is not able to speak complete sentences without taking a breath. This finding is very important in the assessment of your patient because it indicates there is not enough oxygen available to the patient to speak effectively.

2. What can you learn about the patient from his surroundings?

The scene assessment gives numerous indications that the patient has a substantial medical history. The first significant finding is you were met at the door by a neighbor. The neighbor tells you the patient has had medical issues and lives alone. After you enter the residence, you observe multiple medication containers and an abundance of used facial tissues adjacent to the patient. These items need to be investigated further. The patient is also wearing a nasal cannula attached to a home oxygen unit, which indicates a preexisting respiratory condition.

3. How does the recruitment of accessory muscles facilitate breathing?

As you have learned, the act of breathing relies on positive and negative pressures. The chest and other related muscles expand and contract to create the pressure. When the act of breathing becomes difficult, accessory muscles assist with the mechanical aspect of breathing. The nasal passages will flare in an attempt to gain as much space as possible to increase airflow into the airways. Musculature in the chest will work visibly harder to move the chest wall and diaphragm to help create the pressure gradient necessary for breathing. Sitting upright aligns the airway to decrease the amount of pressure needed within the chest.

4. How might the productive cough help you identify the source of the patient's breathing difficulty?

The productive cough could indicate many disease processes. The color of the sputum is of particular interest in your assessment. Thick green, brown, or yellow sputum may indicate infection. Pink, frothy sputum indicates pulmonary edema. Hemoptysis may indicate trauma or carcinoma. After you assess the color, determine how much of it is present. In this case, the numerous used facial tissues can help indicate an amount.

5. On the basis of what you know about physiology, what is causing the pink, frothy sputum?

Pink, frothy sputum is an indication of pulmonary edema that, in this case, may be a sign of

exacerbation of heart failure. If the left ventricle of the heart is not pumping effectively, then blood backs up in the system. The result of the backup causes an increase in pressure within the pulmonary vasculature. The increased pressure forces fluid through the alveolar membrane and into the alveoli. Blood will enter the alveoli through the alveolar membrane in small amounts, producing a pink rather than red appearance. The froth comes from the additional fluid being exposed to the air in the patient's lungs and airways.

6. How do you account for the decreased Spo₂ level?

In this case, the patient would have a decreased amount of surface area for oxygen exchange due to pulmonary edema. Less surface area means less oxygen will "saturate" the cells, which in turn will be read by the pulse oximeter as a decrease in saturation. It is important to note that the saturation amount shown on the electronic device represents any gas that is saturating the cells. Oxygen is one of many gases that can affect the reading. In addition, saturation levels may be compromised by the patient's own lack of circulation.

7. Why would a diuretic be prescribed for a patient with heart failure?

If a patient has heart failure, then the heart is not pumping blood effectively. This causes a backup within the circulatory system, which in turn causes fluid to back up into the pulmonary vasculature. A diuretic helps to eliminate some of the fluid from the system to lessen the workload on the heart. Most diuretics work on the kidneys to eliminate water and electrolytes. The elimination moves fluid from the extracellular to the intravascular space, which will transport it out of the body. The goal is to reduce the cardiac preload, which will reduce the amount of work the cardiac system has to do and reduce the fluid backup.

8. Why would this patient have a normal or slightly high blood pressure?

In patients with heart failure, the heart is working harder to pump fluid volume. Increased venous return to the heart increases cardiac preload. The heart muscle stretches in response to the increased amount of fluid. According to the Starling law, the heart muscle will then contract with greater force—up to a point—to expel the fluid. This accounts for a normal or higher blood pressure because the body is trying to compensate for the lack of the heart's muscular ability.

YOU are the Provider **SUMMARY** *continued***EMS Patient Care Report (PCR)**

Date: 08-01-20	Incident No.: 1234	Nature of Call: Difficulty breathing		Location: 420 Beach Street	
Dispatched: 2041	En Route: 2041	At Scene: 2045	Transport: 2105	At Hospital: 2120	In Service: 2135

Patient Information

Age: 72
Sex: M
Weight (in kg [lb]): 80.2 kg (177 lb)

Allergies: No known drug allergies
Medications: Lasix, aspirin, Prilosec
Past Medical History: Heart failure
Chief Complaint: Difficulty breathing

Vital Signs

Arrived to find this 72-year-old man being attended by his neighbor. Pt lives alone in this residence. Pt alert (oriented to person, place, and time). Pt unable to speak in complete sentences due to respiratory effort. Pt states he has not been compliant with his medications for a time. Pt states he has a history of "heart failure" and is using 2 L/min O₂ via cannula. Assessment shows vital signs as above; breath sound assessment shows coarse crackles in all fields. Pt has productive cough with pink, frothy sputum. O₂ via NRM applied at 15 L/min on scene and throughout transport. IV line of NS established TKO. EtCO₂ waveform appears appropriate in shape and reads 36 mm Hg. Treatment per local protocol, radio report during transport, and verbal report to Halifax Health on arrival. Pt transferred to room A-20.

Ready for Review

- Pathophysiology is the study of the physiology of altered functioning in the presence of disease.
- Pathophysiology in the cellular environment includes disturbances in fluid balance and electrolyte imbalances. These various imbalances can upset homeostasis and may result in or contribute to emergency conditions.
- Cellular injury is caused by factors such as hypoxia, chemical exposure, infectious agents, inappropriate immunologic responses, inflammatory responses, genetic factors, nutritional imbalances, physical agents such as radiation, and adverse conditions such as extreme cold.
- When cells are exposed to adverse conditions, cells undergo a process of temporary or permanent adaptation to protect themselves from injury. Examples of adaptation include atrophy, hypertrophy, hyperplasia, dysplasia, and metaplasia.
- Inflammatory response is characterized by both local and systemic effects. Local effects consist of dilation (expansion) of blood vessels and increased vascular permeability. If the inflammatory process is severe, then systemic effects such as fever become evident. The outcome of an inflammation depends on how much tissue damage has resulted from the inflammation.
- Immunologic diseases occur because of hyperactivity or hypoactivity of the immune system. Allergies are acquired following initial exposure to a stimulant known as an allergen. Repeated exposures generate an immune system reaction to the allergen.
- Perfusion is the delivery of oxygen and nutrients to cells, organs, and tissues through the circulatory system. Hypoperfusion occurs when the level of tissue perfusion falls below normal.
- Shock is an abnormal state associated with inadequate oxygen and nutrient delivery to the metabolic apparatus of the cell, resulting in an impairment of cellular metabolism.
- Central shock consists of cardiogenic shock and obstructive shock. Cardiogenic shock occurs when the heart cannot circulate enough blood to maintain adequate peripheral oxygen delivery. Obstructive shock occurs when blood flow within the heart or great vessels (aorta and pulmonary vein) becomes blocked.
- Peripheral shock includes hypovolemic shock and distributive shock. In hypovolemic shock, the circulating blood volume is insufficient to deliver adequate oxygen and nutrients to the body. Distributive shock occurs when there is widespread dilation of the resistance vessels (small arterioles), the capacitance vessels (small venules), or both.
- Multiple organ dysfunction syndrome (MODS) occurs in acutely ill patients and is characterized by the dysfunction of two or more organs that were not affected by the physiologic insult for which the patient was initially being treated. Six organ systems are surveyed to determine whether a patient has MODS and, if so, how high is the risk of mortality: respiratory, hepatic, renal, hematologic, neurologic, and cardiovascular.
- The immune system includes all structures and processes that mount a defense against foreign substances and disease-causing agents.
- The body has three lines of defense: anatomic barriers, the inflammatory response, and the immune response.
- There are two general types of immune response: native and acquired.
- Immunity may be humoral or cell-mediated.
- Important white blood cells in the immune system include neutrophils, eosinophils, basophils, monocytes, and lymphocytes. Other important cells of the immune system include macrophages, mast cells, plasma cells, B cells, and T cells.

- The antibodies secreted by B cells are called immunoglobulins. Antibodies make antigens more visible to the immune system in three ways: by acting as opsonins, by making antigens clump, and by inactivating bacterial toxins.
- The inflammatory response is the reaction of the body's tissues to cellular injury. It is characterized by pain, swelling, redness, and heat.
- The two most common causes of inflammation are infection and injury.
- The plasma protein systems that modulate the inflammatory process include the complement system, the coagulation (clotting) system, and the kinin system.
- Cytokines are products of cells that affect the functioning of other cells; they include interleukins, lymphokines, and interferon.
- Chronic inflammatory responses are usually caused by an unsuccessful acute inflammatory response after the invasion of a foreign body, a persistent infection, or an antigen.
- Normal wound healing involves four steps: repairing damaged tissue, removing inflammatory debris, restoring tissues to a normal state, and regenerating cells.
- Wounds may heal by primary or secondary intention. Healing by primary intention occurs in clean wounds with opposed margins. Wounds that heal by secondary intention have a prolonged inflammatory phase and more abundant granulation tissue.
- Hypersensitivity is an increased response of the body to any substance to which the person is abnormally sensitive. A hypersensitivity reaction may be immediate, occurring within seconds to minutes, or delayed, occurring hours to days after exposure to the antigen.
- Hypersensitivity reactions may be classified as autoimmune, idiopathic, or blood incompatibility reactions.
- Immunodeficiency may be congenital or acquired.
- Age- and sex-associated factors interact with a combination of genetic and environmental factors, lifestyle, and anatomic or hormonal differences to cause disease.
- Analyzing disease risk involves consideration of disease rates (incidence, prevalence, morbidity, and mortality) and controllable and uncontrollable disease risk factors (causal and noncausal). These risk factors, age, and sex differences interact to influence a person's level of risk.
- A true genetic risk is passed through generations on a gene. In contrast, a familial tendency may cluster in family groups despite lack of evidence for heritable gene-associated abnormalities.
- Stress does not cause death directly, but it can permit diseases to flourish, ultimately leading to death.
- The general adaptation syndrome describes the body's short- and long-term reactions to stress.
- Stress causes the sympathetic nervous system to be stimulated. This occurs through the release of catecholamines that activate the sympathetic nervous system by binding to alpha and beta receptor sites, resulting in effects categorized as fight-or-flight response.
- Stress also causes secretion of cortisol, which has many useful effects such as increasing serum glucose levels, decreasing protein reserves, and permitting mobilization of fatty acids. However, continuous secretion of cortisol has deleterious effects.

Vital Vocabulary

acidosis A pathologic condition that results from the accumulation of acids in the body; an increase in extracellular H^+ ions; a blood pH of less than 7.35.

acquired immunity The immunity that occurs when the body is exposed to a foreign substance antigen, or disease, and produces antibodies to the invader.

activation Mediators of inflammation trigger the appearance of molecules known as selectins and integrins on the surfaces of endothelial cells and polymorphonuclear neutrophils, respectively.

adhesion The attachment of polymorphonuclear neutrophils to endothelial cells, mediated by selectins and integrins.

alcoholic ketoacidosis The metabolic acidotic state that manifests because of the inadequate nutritional habits associated with chronic alcohol abuse. The liver and body experience inadequate fuel reserves of glycogen and, thus, have to switch to fatty acid metabolism.

alkalosis A pathologic condition resulting from the accumulation of bases in the body; a decrease in extracellular H^+ ions; a blood pH greater than 7.45.

allergen Any substance that causes a hypersensitivity reaction.

allergy A hypersensitivity reaction to the presence of an agent (allergen) that is intrinsically harmless.

anaphylactic shock Severe shock caused by an allergic reaction; a severe hypersensitivity reaction that involves bronchoconstriction and cardiovascular collapse.

angiogenesis The growth of new blood vessels.

antibody A protein secreted by certain immune cells that bind antigens to make them more visible to the immune system; an immunoglobulin.

antigen An agent that, when taken into the body, stimulates the formation of specific protective proteins called antibodies.

apoptosis Normal, genetically programmed cell death.

asthma A chronic inflammatory lower airway condition resulting in intermittent wheezing and excess mucus production; muscle spasm in the small air passageways and excess mucus result in airway obstruction.

atopic An allergic tendency.

atrophy A decrease in cell size due to a loss of subcellular components.

autoantibodies Antibodies directed against the person's own proteins.

autoimmunity The production of antibodies or T cells that work against the tissues of a person's body, producing autoimmune disease or a hypersensitivity reaction.

bradypnea Slow respiratory rate; ominous sign in a child; indicates impending respiratory arrest.

capillary refill time The amount of time that it takes for blood to return to the capillary bed after applying pressure to the skin or nail bed; indicates the status of end-organ perfusion; reliable in children younger than 6 years.

cardiogenic shock Shock caused by inadequate function of the heart, or pump failure; caused by loss of 40% or more of the functioning myocardium; the heart is no longer able to circulate sufficient blood to maintain adequate oxygen delivery; can be a severe complication of a large acute myocardial infarction, as well as other conditions.

carpopedal spasm A contorted position of the hand or foot in which the fingers or toes flex in a clawlike manner; may result from hyperventilation or hypocalcemia.

cell-mediated immunity The immune process by which T-cell lymphocytes recognize antigens and then secrete cytokines (specifically lymphokines) that attract other cells or stimulate the production of cytotoxic cells that kill the infected cells.

central shock A type of shock caused by central pump failure, including cardiogenic shock and obstructive shock.

chemotaxins Components of the activated complement system that attract leukocytes from the circulation to help fight infections.

chemotaxis The movement of additional white blood cells to an area of inflammation in response to the release of chemical mediators, such as neutrophils, injured tissue, and monocytes.

coagulation system The system that forms blood clots in the body and facilitates repairs to the vascular tree.

complement system A group of plasma proteins whose function is to do one of three things: attract leukocytes to sites of inflammation, activate leukocytes, and directly destroy cells.

cytokines The products of cells that affect the function of other cells.

distributive shock The type of shock caused by widespread dilation of the resistance vessels (small arterioles), the capacitance vessels (small venules), or both.

dysplasia An alteration in the size, shape, and organization of cells.

edema The presence of abnormally large amounts of fluid between cells in body tissues, causing swelling of the affected area.

fibrin A white, filamentous protein formed by the action of thrombin on fibrinogen; the protein that polymerizes (bonds) to form the fibrous component of a blood clot.

fibrinolysis cascade The breakdown of fibrin in blood clots and the prevention of the polymerization of fibrin into new clots.

free radical A molecule that is missing one electron in its outer shell.

general adaptation syndrome The body's response to stress that begins with an alarm response, followed by a stage of reaction and resistance, and then recovery or, if the stress is prolonged, exhaustion.

haptan A substance that normally does not stimulate an immune response but can be combined with an antigen and at a later point initiate an antibody response.

helper T cell A type of T lymphocyte that is involved in cell-mediated and antibody-mediated immune responses. It secretes cytokines that stimulate the B cells and other T cells.

hemochromatosis An inherited disease in which the body absorbs more iron than it needs and stores it in the liver, kidneys, and pancreas.

hemolytic anemia A disease characterized by increased destruction of the red blood cells. It

can occur from an Rh factor reaction (primarily in Rh-positive neonates born to sensitized Rh-negative mothers), exposure to chemicals, or a disorder of the immune system.

hemophilia A congenital abnormality in which the body is unable to produce clots due to a lack of normal clotting factors, resulting in uncontrollable bleeding.

histamine Chemical substance released by the immune system in allergic reactions that is responsible for many of the symptoms of anaphylaxis, such as vasodilation; increases vascular permeability and tissue inflammation; found in large amounts in basophils.

humoral immunity A type of immunity in which B-cell lymphocytes produce antibodies called immunoglobulins, which recognize a specific antigen and then react with it.

hypercalcemia An elevated blood calcium level.

hypercholesterolemia An elevated blood cholesterol level.

hyperkalemia An elevated serum potassium level.

hypermagnesemia An increased serum magnesium level.

hypernatremia A serum sodium level greater than or equal to 143 mEq/L.

hyperphosphatemia An elevated serum phosphate level.

hyperplasia An increase in the actual number of cells in an organ or tissue, usually resulting in an increase in the size of the organ or tissue.

hypersensitivity Abnormal sensitivity; a condition in which the body manifests an exaggerated response to the stimulus of a foreign agent.

hypertrophy An increase in the size of the cells due to synthesis of more subcellular components, leading to an increase in tissue and organ size.

hypocalcemia A decreased serum calcium level.

hypokalemia A decreased serum potassium level.

hypomagnesemia A decreased serum magnesium level.

hyponatremia A serum sodium level that is less than or equal to 135 mEq/L.

hypoperfusion A condition that occurs when the level of tissue perfusion decreases below that needed to maintain normal cellular functions.

hypophosphatemia A decreased serum phosphate level.

hypothalamic-pituitary-adrenal axis A major part of the neuroendocrine system that controls reactions to stress. It is the mechanism for a set of interactions among glands, hormones, and parts of the midbrain that mediate the general adaptation syndrome.

hypovolemic shock A condition in which low blood volume, due to massive internal or external bleeding or extensive loss of body water, results in inadequate perfusion.

immune response The body's defense reaction to any substance that is recognized as foreign.

immune system The body system that includes all of the structures and processes designed to mount a defense against foreign substances and disease-causing agents.

immunodeficiency An abnormal condition in which some part of the body's immune system is inadequate, and, consequently, resistance to infectious disease is decreased.

immunogen An antigen that is capable of generating an immune response.

immunoglobulins Antibodies secreted by the B cells.

incidence The number of new cases of a disease in a population.

inflammatory response A reaction by tissues of the body to irritation or injury, characterized by pain, swelling, redness, and heat.

interferon A protein produced by cells in response to viral invasion that is released into the bloodstream or intercellular fluid to induce

healthy cells to manufacture an enzyme that counters the infection.

interleukins Chemical substances that attract white blood cells to the sites of injury and bacterial invasions.

isoimmunity The formation of antibodies or T cells that are directed against antigens or another person's cells.

ketoacidosis An acidotic state created by the production of ketones via fat metabolism.

ketones Acidic by-products of fat metabolism.

killer T cells The cells released during a type IV allergic reaction that kill antigen-bearing target cells.

kinin system A group of polypeptides that mediate inflammatory responses by stimulating visceral smooth muscle and relaxing vascular smooth muscle to produce vasodilation.

lactic acidosis Anaerobic cellular respiration due to hypoperfusion of tissues and organs.

leukocytosis An elevated white blood cell count, often due to inflammation.

leukotrienes Arachidonic acid metabolites that function as chemical mediators of inflammation; also known as slow-reacting substances of anaphylaxis.

lymphokines Cytokines released by lymphocytes, including many of the interleukins, gamma interferon, tumor necrosis factor beta, and chemokines.

margination The loss of fluid from the blood vessels into the tissue, causing the blood left in the vessels to have increased viscosity, which in turn slows the flow of blood and produces stasis.

membrane attack complex Molecules that insert themselves into the bacterial membrane, leading to weakened areas in the membrane.

metabolic acidosis A pathologic condition characterized by a blood pH of less than 7.35 and caused by an accumulation of acids in the body from a metabolic cause.

metabolic alkalosis A pathologic condition characterized by a blood pH of greater than 7.45 and caused by an accumulation of bases in the body from a metabolic cause.

metaplasia A reversible, cellular adaptation in which one adult cell type is replaced by another adult cell type.

morbidity Number of nonfatally injured or disabled people; usually expressed as a rate, meaning the number of nonfatal injuries in a certain population in a given time period divided by the size of the population.

morbid obesity An excessively unhealthy accumulation of body fat, defined as a body mass index of greater than or equal to 40 kg/m².

mortality The quality of being mortal; number of deaths from a disease in a given population.

multiple organ dysfunction syndrome (MODS) A progressive condition that occurs after severe illness or injury, usually characterized by combined failure of two or more organs or organ systems not affected by the patient's initial illness or injury, along with some clotting mechanisms.

natural immunity A nonspecific cellular and humoral response that operates as the body's first line of defense against pathogens; this develops as part of being exposed to an antigen and developing antibodies; also called native immunity.

necrosis The death of tissue, usually caused by a cessation of the blood supply.

neurogenic shock Circulatory failure caused by paralysis of the nerves that control the size of the blood vessels, resulting in widespread vasodilation and loss of sympathetic nervous system tone; seen in patients with spinal cord injuries.

obesity A complex condition in which a person has an excessive amount of body fat; the result of an imbalance between calories consumed and calories used; defined as a body mass index of greater than or equal to 30 kg/m².

obstructive shock Shock that occurs when there is a block to blood flow in the heart or great

vessels, causing an insufficient blood supply to the body's tissues.

oliguria A decrease in urine output to the extent that total urine output drops to less than 500 mL per day.

opsonization The process by which an antibody coats an antigen to facilitate its recognition by immune cells.

overweight An unhealthy accumulation of body fat, defined as a body mass index of 25 to 29.9 kg/m².

pathophysiology The study of the physiology of altered functioning in the presence of disease.

perfusion The circulation of oxygenated blood within an organ or tissue in adequate amounts to meet the cells' current needs.

pericardial tamponade The impairment of diastolic filling of the right ventricle due to significant amounts of fluid in the pericardial sac surrounding the heart, leading to a decrease in the cardiac output.

peripheral shock Shock caused by peripheral circulatory abnormalities; includes hypovolemic shock and distributive shock.

phagocytes The cells that engulf and consume foreign material such as microorganisms and debris.

polymorphonuclear neutrophils (PMNs) The type of white blood cells formed by bone marrow tissue that have a nucleus consisting of several parts or lobes connected by fine strands.

polyuria The passage of an unusually large volume of urine in a given period; in diabetes, this can result from wasting of glucose in the urine.

prevalence The number of cases of a disease in a specific population within a given period.

prostaglandins A group of lipids that act as chemical messengers.

pyrogens Chemicals or proteins that travel to the brain and affect the hypothalamus and stimulate a rise in the body's core temperature.

receptor A specialized area in tissue that initiates certain actions after specific stimulation.

respiratory acidosis A pathologic condition characterized by a blood pH of less than 7.35 and caused by accumulation of acids in the body from a respiratory cause such as inadequate ventilation.

respiratory alkalosis A pathologic condition characterized by a blood pH of greater than 7.45 and caused by an accumulation of bases in the body from a respiratory cause such as overaggressive ventilation.

septic shock The type of shock that occurs as a result of widespread infection, usually bacterial; untreated, the result is multiple organ dysfunction syndrome and often death.

serotonin A vasoactive amine that increases vascular permeability to cause vasodilation.

serum sickness A condition in which antigen-antibody complexes formed in the bloodstream deposit in sites around the body, most notably the kidneys, with resultant inflammatory reactions.

transmigration (diapedesis) The polymorphonuclear neutrophils permeate through the vessel wall, moving into the interstitial space.

urticaria Small areas of generalized itching and/or burning that appear as multiple raised areas on the skin; hives. May be one of the warning signs of impending anaphylaxis.

vasculitis An inflammation of the blood vessels.

vasoactive amines Substances such as histamine and serotonin that increase vascular permeability.

virulence A measure of the disease-causing ability of a microorganism.

Chapter 9

Life Span Development

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Life Span Development

Applies fundamental knowledge of life span development to patient assessment and management.

KNOWLEDGE OBJECTIVES

1. Know the terms used to designate the following developmental stages: infants, toddlers, preschoolers, school-age children, adolescents (teenagers), early adults, middle adults, and older adults. (pp 430, 434, 437, 439, 440)
2. Describe the major physical and psychosocial characteristics of an infant's life. (pp 430–434)
3. Describe the major physical and psychosocial characteristics of a toddler's life. (pp 434–436)
4. Describe the major physical and psychosocial characteristics of a preschooler's life. (pp 434–436)
5. Describe the major physical and psychosocial characteristics of a school-age child's life. (p 437)
6. Describe the major physical and psychosocial characteristics of an adolescent's life. (pp 437–438)
7. Describe the major physical and psychosocial characteristics of an early adult's life. (pp 439–440)
8. Describe the major physical and psychosocial characteristics of a middle adult's life. (p 440)
9. Describe the major physical and psychosocial characteristics of an older adult's life. (pp 440–445)

SKILLS OBJECTIVES

There are no skills objectives for this chapter.

Introduction

One of the most interesting things about humans is that we evolve throughout our life spans—not just as a species, but also as people. Advanced emergency medical technicians (AEMTs) must be aware of the obvious *and* the subtle changes a person undergoes physically and mentally at various stages of life and understand how these changes might alter the approach to patient care.

Neonates (Birth to 1 Month) and Infants (1 Month to 1 Year)

As any parent can attest, infants develop at a startling rate (**FIGURE 9-1**). The word **infant** describes a child who is 1 month to 1 year of age. From birth to 1 month, the child is termed a **neonate**. Neonatal issues and care are covered in detail in Chapter 35, *Obstetrics and Neonatal Care*.

Physical Changes

Vital Signs

Normal ranges for vital signs are different across various age groups. The general rule is the younger the person, the faster the pulse rate and respirations. At birth, a pulse rate of 100 to 205 beats/min and a respiratory rate of 30 to 60 breaths/min are considered normal. Within the first half hour after birth, a neonate's pulse rate usually drops to 120 beats/min and the respiratory rate falls to between 30 to 40 breaths/min. By age 1 year, the respiratory rate slows to 20 to 30 breaths/min. The tidal volume in neonates starts at 6 to 8 mL/kg. By the end of the first year, the volume increases to 10 to 15 mL/kg. Normal vital sign ranges are outlined in

FIGURE 9-1 An infant.

© Johanna Goodyear/Shutterstock.

Chapter 10, *Patient Assessment*, and Chapter 36, *Pediatric Emergencies*.

Blood pressure directly corresponds to the patient's weight, so it typically increases with age. At birth, the average systolic blood pressure of a neonate is 67 to 84 mm Hg. By 1 year of age, it ranges between 85 and 104 mm Hg. A neonate's normal body temperature ranges from 98°F (37°C) to 100°F (38°C).

YOU are the Provider

Part 1

You and your partner are dispatched to a local residence for a 3-month-old girl who has a runny nose. On arrival, you are met at the door by the mother who is holding the infant in her arms. The scene is safe and the house appears to be neat and clean. The patient's mother introduces her older adult mother, for whom she also provides care, as well as a 12-year-old sibling.

1. How does the patient's age affect your treatment?
2. What are some physical differences between pediatric and adult patients?

An infant's normal temperature ranges between 96.8°F (36°C) to 99.6°F (37.5°C).

Words of Wisdom

Infants often land head-first when they fall because their heads account for 25% of their total body weight. Also, most infants cannot stretch out their arms in time to cushion or slow their fall. Keep this in mind when considering spinal immobilization of an infant.

Weight

A neonate usually weighs 6 to 8 pounds (3 to 3.5 kg) at birth. Remarkably, the head accounts for 25% of an infant's total body weight. In the first week after birth, neonates will usually have a 5% to 10% birth weight loss due to the loss of fluids. By week 2, the neonate begins to gain weight. From here on, infants grow at a rate of about 1 ounce (30 g) per day, doubling their weight within 4 to 6 months and tripling it by the end of the first year.

Cardiovascular System

Before birth, fetal circulation occurs through the placenta. During the birthing process, hormones and pressure changes help the neonate make the transition from fetal circulation to independent circulation. Chapter 35, *Obstetrics and Neonatal Care*, covers the transition from fetal circulation.

Pulmonary System

Before a neonate's first breath, the lungs have never been inflated. For this reason, a neonate's first breath must be forceful.

Neonates are primarily nose breathers. Infants younger than 6 months are particularly susceptible to nasal congestion, which can cause viral upper respiratory infections. If you receive a call for a baby choking, ensure the nasal passages are clear and unobstructed by mucus.

The rib cage of an infant is less rigid than an adult's, and the ribs sit horizontally. This explains the diaphragmatic breathing (belly breathing) in infants. Owing to the immaturity of the accessory muscles, fatigue sets in quickly.

Special Populations

When you are counting respirations in an infant, count the number of times the abdomen rises instead of concentrating solely on the chest rise.

Words of Wisdom

Fluid and heat loss occur through exhalation. The rapid respiratory rate of infants can lead to significant heat and fluid loss. Keep infants warm and monitor them for signs of dehydration.

Two other important anatomic points related to an infant's airway, compared with an adult's, are the proportionally large size of the tongue and the proportionally shorter, narrower, and less stable airway. As a result, the airway in infants can be obstructed much more easily than in older children and adults. There are also fewer alveoli in the lungs, which decreases the surface area for gas exchange. When stressed, the respiratory system's ability to compensate is limited. Respiratory problems in infants can rapidly become life threatening.

When providing bag-mask ventilations to an infant, be aware that an infant's lungs are fragile. Ventilations that are too forceful can result in trauma from pressure, or barotrauma (**FIGURE 9-2**).

FIGURE 9-2 An infant's lungs are fragile. Use caution when providing bag-mask ventilations to avoid barotrauma.

© Jones and Bartlett Learning.

Barotrauma is trauma resulting from increased pressure, for example, from too much pressure in the lungs. Also pay close attention to the position of the airway when providing ventilations. Due to factors such as the proportionally oversized occiput, the increased flexibility of the trachea, and an infant's limited or absent ability to reposition, it is crucial to preserve the airway's patency through proper positioning. Hyperextending or hyperflexing an infant's head and neck can easily produce an airway obstruction.

Nervous System

Although an infant's nervous system is developed at birth, it continues to evolve after birth. For example, neonates lack the ability to localize and isolate a particular response to sensation. When neonates are born, they tend to move their extremities together in response to stimulation. Motor and sensory development are most developed in the cranial nerves, allowing for strong, coordinated sucking and gag reflexes.

A neonate is born with certain reflexes. The **Moro reflex** (startle reflex) happens when a neonate is surprised by something or someone; the neonate opens the arms wide, spreads the fingers, and seems to grab at things. A **palmar grasp** occurs when an object is placed into the neonate's palm. The **rooting reflex** takes place when something touches a neonate's cheek; the neonate will instinctively turn the

head toward the touch. In conjunction with the **sucking reflex**, which occurs when an infant's lips are stroked, these reflexes are often evident when feeding.

A neonate's **fontanelles** allow the head to be molded—for example, when the neonate passes through the birth canal (**FIGURE 9-3**). The fontanelles are the area or space between the bones that eventually fuse to form the skull. The three or four bones of the skull eventually bind together and form suture joints. The posterior fontanelle normally fuses by 3 months of age. The anterior fontanelle fuses between 9 and 18 months of age. If either of the fontanelles is depressed when you assess the head, the infant is most likely dehydrated. A bulging fontanelle is indicative of increased intracranial pressure.

Special Populations

Use the fontanelles of infants as an assessment tool: bulging fontanelles may indicate increased intracranial pressure and sunken fontanelles are indicative of dehydration.

Perhaps the neurologic development that is of most interest to parents is the development of a sleep pattern. Some physicians suggest parents

FIGURE 9-3 Fontanelles.

wake neonates and infants every few hours for feeding and safety (for example, to guard against sudden infant death syndrome, commonly known as SIDS). Others suggest neonates and infants should be left to sleep so they can adjust to family life and develop a circadian rhythm, ideally within 4 months after birth. SIDS is described in more detail in Chapter 36, *Pediatric Emergencies*.

Musculoskeletal System

Growth plates (also known as epiphyseal plates or physes), located on either end of an infant's long bones, aid in lengthening a child's bones.¹ Bones grow in thickness by building on themselves.

Renal System

Infants can become dehydrated easily because their kidneys usually cannot produce concentrated urine. An infant's urine consists mainly of water, which can cause the development of electrolyte imbalances.

Immune System

While in the womb, fetuses collect antibodies from the maternal blood. For the first 6 months of life, the infant maintains some of the mother's immunities, so the infant has naturally acquired passive immunities. Infants can also receive antibodies via breastfeeding, further bolstering their immune system.

Psychosocial Changes

An infant's psychosocial development begins at birth and continues to evolve as the infant interacts with and reacts to the environment. Rapid changes occur during the first year of life. Parents are often very concerned with whether their children are developing within the socially accepted norms. **TABLE 9-1** outlines the typical ages when major psychosocial changes are noticed.

For most infants, the primary method of communicating distress is through crying. Parents can often tell what is upsetting their children simply by listening to the tone of their cries—that is, they know the difference between a basic cry expressing frustration, fear, hunger, discomfort, and sleepiness and the tears that indicate anger or pain. Infants occasionally make another distinct cry—an alarming distressed cry. This cry may be heard when an

TABLE 9-1 Noticeable Characteristics at Various Ages

Age	Characteristic
2 months	Recognizes familiar faces; tracks objects with eyes
3 months	Brings objects to the mouth; smiles and frowns
4 months	Reaches out to people; drools
5 months	Sleeps throughout the night; recognizes family members from strangers
6 months	Teething begins; sits upright; speaks one-syllable words
7 months	Afraid of strangers; mood swings
8 months	Responds to “no”; can sit alone; plays peek-a-boo
9 months	Pulls up to a stand; places objects in mouth to explore them
10 months	Responds to own name; crawls efficiently
11 months	Tries to walk without help; frustrated with restrictions
12 months	Knows own name; walks

© Jones & Bartlett Learning.

unexpected event occurs, causing a situational crisis for the infant.

One key to having a happy, healthy infant is spending time with the infant. Nevertheless, infants often have their own timetable as to when they will become attached to their parents and other family members. **Bonding**, or the formation of a close, personal relationship, is usually based on a secure attachment. A **secure attachment** occurs when infants understand that parents or caregivers will be responsive to their needs. This realization encourages infants to reach out and explore, knowing their parents will provide a safety net.

Another type of attachment, referred to as **anxious-avoidant attachment**, is observed in infants who are repeatedly rejected. In this attachment style, infants show little emotional response to their parents or caregivers and treat them as they would strangers. These children often develop an isolated

FIGURE 9-4 Protesting and crying in reaction to unfamiliar places and people is a normal reaction in older infants.

© Scot Milless/Shutterstock.

lifestyle where they do not have to depend on the support and care of others.

Separation anxiety is common in older infants (10 to 18 months). The infant may exhibit clingy behavior and fear of unfamiliar places and people. Protesting by crying is another normal reaction in older infants (**FIGURE 9-4**). As infants become accustomed to their homes and families, they begin to need the security of a predictable environment. If an infant's environment is too unpredictable, the infant may despair and become withdrawn, which leads to trust issues.

The concept of **trust and mistrust** describes a stage of development from birth to about 18 months of age. Most infants desire that their world be planned, organized, and routine. When their caregivers and parents provide this environment for them, infants gain trust in those people. If the infant does not perceive the environment as secure, a sense of mistrust will develop.

Words of Wisdom

When assessing infants and toddlers, remember that these age groups can experience falls and injuries as a result of their developmental stage (for example, learning to walk or climb). Also remember that they can be victims of abuse and neglect. Look for injuries that are not consistent with the developmental stage, for example, a 15-month-old may climb out of a crib and sustain injuries as a result of a fall, but a 4-month-old cannot climb out of a crib.

Toddlers (1 to 3 Years) and Preschoolers (3 to 6 Years)

Physical Changes

In a **toddler** (1 to 3 years), the pulse rate is 80 to 140 beats/min and the respiratory rate is 22 to 37 breaths/min, slower than the corresponding vital signs in infants, whereas the systolic blood pressure is higher (86 to 106 mm Hg). The average temperature of children this age is 96.8°F (36°C) to 99.6°F (38°C), usually leveling off at 98.6°F (37°C) by preschool age (**FIGURE 9-5**).

In a **preschooler** (3 to 6 years), the pulse rate is 65 to 120 beats/min and the respiratory rate is 20 to 28 breaths/min. The systolic blood pressure is 89 to 112 mm Hg. At the same time, weight gain should level off (**FIGURE 9-6**).

A toddler's cardiovascular system is not dramatically different from an adult's. A toddler's lungs continue to develop more terminal bronchioles and alveoli. Although toddlers and preschoolers have more lung tissue, they do not have well-developed lung musculature. This characteristic prevents them from sustaining deep or rapid respirations for an extended period.

FIGURE 9-5 A toddler.

Street Smarts

Allow children to remain near family members to decrease anxiety. Invite them to hold or examine medical equipment to reduce their fears of the unknown. In a nonemergency situation, give the child the opportunity to listen to your heartbeat before listening to the child's. You may also "perform" an examination on a favorite doll or stuffed animal to demonstrate for the child and lessen mistrust.

The loss of passive immunity in the immune system is possibly the most obvious development at this stage of human life. Viral infections (colds) often develop that may manifest as gastrointestinal distress or upper respiratory tract infections. As toddlers spend more time around playmates and classmates, they acquire immunities as their bodies are exposed to various viruses and germs.

Neuromuscular growth also makes considerable progress at this age. Toddlers and preschoolers spend a great deal of time finding out exactly how to use their expansive nervous system and the muscles it controls by walking, running, jumping, and playing catch (**FIGURE 9-7**). Watching the changes in how children play as they age from 1 to 6 years

FIGURE 9-7 A toddler learns to walk, one of the major milestones in life.

© monkeybusinessimages/Stock/Getty Images.

demonstrates how they move from gross motor activities (grabbing an object with the full palm) to fine motor activities (picking up a crayon). By the end of this stage, preschoolers will have a brain that weighs 90% of its final adult weight. In addition, all of this play places stress on the muscles and bones. Consequently, muscle mass increases, as does bone density.

This stage also includes the continued development of the renal system and of elimination patterns (ie, toilet training). Physiologically, toddlers have the neuromuscular control needed for bladder control by 12 to 15 months of age. However, the child may not be psychologically ready until 18 to 30 months of age. The average age for completion of toilet training is 28 months of age, but it depends on the individual child.

Other developments that occur during this time frame include the emergence of primary (baby) teeth. Teething (that is, teeth breaking through the gums) can be painful and accompanied by fever. In addition, parents and toddlers are enthralled with sensory development—for example, as shown by tickling. According to the Centers for Disease Control and Prevention (CDC), the leading cause of death for this age group is unintentional injuries (accidents).²

Safety

Do not discount the possibility of an infectious disease in children. Use standard precautions when treating all patients to protect yourself and others.

Psychosocial Changes

This period of development is often exciting for parents. Toddlers or preschoolers are continuing to learn to speak and express themselves, thereby taking a major step toward independence. The psychosocial challenge for this age group is sometimes referred to as autonomy versus shame and doubt. Through milestones such as speech development and toilet training, the child begins to attain a measure of self-sufficiency. At the same time, toddlers are very attached to their parents and feel safe with them. Separation anxiety peaks between 10 and 18 months of age. It is fascinating to watch a child struggle through the conflict of wanting to play, yet wanting to be protected.

At 36 months of age, in most toddlers, basic language is mastered. Refinement of this skill is continued throughout childhood. By the age of 3 or 4 years, most children can use and understand full sentences. As they progress through this stage, they will transition from using language to communicate what they want to using language creatively and playfully.

This is also the time when toddlers begin to interact with other children and start to play games. Playing games teaches control, following of rules, and even competitiveness. Significant learning and development take place as children watch their peers during group outings, such as “play dates” with other children. By 18 to 24 months, toddlers begin to understand cause and effect. They learn the negative and positive consequences of their actions. For example, “If I move this lever, the water turns on” or “If I take my bath nicely, I will get to listen to a story.” Of course, behavior observed on television and computers can also be learned, which is why some parents limit their children’s viewing choices or the amount of time they devote to these activities. During this phase of development, children also learn to recognize sexual differences by observing their role models.

Street Smarts

When responding to a severely sick or injured child, you may encounter multiple patients—the child and the parents. The sudden stress, fear, and uncertainty can be overwhelming, causing panic. The parents’ distress can add to an already intense situation, upsetting the child and making it much more difficult to treat the patient.

YOU are the Provider**Part 2**

The infant appears listless and will only awaken with stimulation. As you are gathering additional information from the mother, the 12-year-old brother comes over and seems very interested in what is going on.

Recording Time: 0 Minute

Appearance	Lethargic
Level of consciousness	Awakens with tactile stimulation
Airway	Thick, yellow secretions from both nares
Breathing	Labored
Circulation	Rapid brachial pulses, cyanosis around the lips

- Why are the secretions around the infant’s nares significant?
- What are some common psychosocial concerns experienced by pediatric patients?

School-Age Children (6 to 12 Years)

Physical Changes

During **school age**, from age 6 to 12 years, a child's vital signs and body gradually approach those observed in adulthood (**FIGURE 9-8**). The pulse rate is approximately 58 to 118 beats/min, the respiratory rate is 18 to 25 breaths/min, and the systolic blood pressure is 97 to 120 mm Hg. Obvious physical traits and body function changes become apparent as most children gain about 4 pounds (2 kilograms) and grow 2.5 inches (6 centimeters) each year. Brain function develops further in both hemispheres, and permanent teeth begin to replace children's primary teeth during this period. The CDC cites unintentional injuries as the leading cause of death in this age group.²

Psychosocial Changes

School-age children are engaged in a lot of psychosocial growth. Parents generally do not devote as much time to their children during this phase as they did in earlier phases. Nevertheless, it is at this crucial time in human development that children learn various types of reasoning. In **preconventional**

reasoning, children act almost purely to avoid punishment and to get what they want. In **conventional reasoning**, they look for approval from their peers and society. In **postconventional reasoning**, children make decisions guided by their conscience.

During school age, children compare themselves with the adults and other children they interact with daily. Through these comparisons, they begin to develop their self-concept and self-esteem. *Self-concept* is our perception of ourselves; *self-esteem* is how we feel about ourselves and how we “fit in” with our peers.

Adolescents (12 to 18 Years)

Physical Changes

In an **adolescent** (12 to 18 years), vital signs begin to level off within the adult ranges, with a pulse rate between 50 to 100 beats/min, respirations in the range of 12 to 20 breaths/min, and a systolic blood pressure generally between 110 and 131 mm Hg (**FIGURE 9-9**).

Adolescence is also the time of life when humans experience a rapid, 2- to 3-year growth spurt (ie, an increase in muscle and bone growth) and body changes. Growth begins with hands and feet, then moves to the long bones of the extremities,

FIGURE 9-8 A school-age child.

© Trout55/Shutterstock.

FIGURE 9-9 An adolescent.

© Jamie Wilson/Shutterstock.

and finishes with growth of the torso. Boys typically experience this growth spurt later in life than girls. Girls usually finish their growth spurt by 16 years of age and boys by 18 years of age. When this period of growth has finished, however, boys are generally taller than girls. Muscle mass and bone density are nearly at adult levels.

One change during adolescence is the maturation of the human reproductive system. Secondary sexual development begins, including the enlargement of the external reproductive organs. Pubic hair and axillary hair begin to appear. Voices start to change in range and depth. In girls, the breasts and thighs increase in size as adipose (fat) tissue is deposited there. Menstruation begins during this time. Menarche, the first menstrual bleeding, occurs during this time; however, it is not uncommon for menstruation to begin before a girl becomes a teenager.

These changes in the endocrine and reproductive systems provide the platform for reproduction. By the middle of adolescence, boys produce sperm and a girl's ovaries start releasing eggs for fertilization. Acne can also occur due to hormonal changes. The CDC reports unintentional injuries are also the leading cause of death for adolescents.²

Psychosocial Changes

Adolescents and their families often deal with conflict as adolescents try to gain control of their lives and independence from their parents. Privacy becomes an important issue among adolescents, their siblings, and their parents. Self-consciousness also increases. Adolescents may struggle to create their identities—to define themselves (**FIGURE 9-10**), for example, by dressing in a certain style of clothing to fit their personalities. Adolescents use the feedback from their families and peers to help create their adult image. Adolescents are often caught between two worlds. They want to be treated like adults yet want to be cared for like younger children.

Rebellious behavior can be part of adolescents trying to find their own identity. Adolescents continually compare themselves with their peers, which makes peer pressure a major factor in adolescents' psychological growth. Antisocial behavior peaks during the eighth or ninth grade. Adolescence is also a time when eating disorders may develop as teenagers exhibit self-control through what they eat or become obsessed with body image.

FIGURE 9-10 Adolescents want to fit in and may struggle to create their identities.

© Monkey Business Images/Shutterstock.

Self-destructive behaviors such as smoking, drinking, sex, and other high-risk behaviors may begin. Although these behaviors can be very troubling to parents, adolescents are trying to determine if they are ready to take control of their own life. An adolescent's struggle toward independence may include setbacks that can be devastating. Patience and support from family and friends are essential in assisting an adolescent's transition into adulthood.

Adolescents may also show greater interest in sexual relations. Many adolescents are fixated on their public image and are terrified of being embarrassed. At this age, a code of personal ethics is developed, based partly on parents' ethics and values and partly on the influence of the adolescent's environment. At this tumultuous time, teenagers are at a higher risk than other populations for suicide and depression.

Special Populations

When you interview adolescents, treat them as adults to gain better cooperation and honesty. Allow them to express their opinions about the care they will receive, and permit them to voice any disapproval. It is also important to allow them the opportunity to speak privately. Most teenagers feel uncomfortable discussing certain problems in front of their parents. They may even deny any problem to avoid the embarrassment of the situation. However, it is important to remember, you are ultimately still dealing with a child, and in most cases, a parent will be required to authorize treatment.

Early Adults (19 to 40 Years)

Physical Changes

The term **early adult** applies to people from 19 to 40 years of age (**FIGURE 9-11**). Their vital signs do not vary greatly from those seen throughout adulthood. Ideally, the human pulse rate will stay around 70 beats/min, the respiratory rate will stay in the range of 12 to 20 breaths/min, and the systolic blood pressure will be approximately between 90 and 140 mm Hg.

From age 19 years to shortly after 25 years, the human body should be functioning at its optimal level. Lifelong habits and routines develop at this age, including eating preferences, exercise, and tobacco use.

At the beginning of the early adult period, the body is working at peak efficiency, but as early adulthood continues, subtle wear and tear on bones and changes in body tissues and muscles begin. The disks in the spine begin to settle, and height can sometimes be affected, causing “shrinking.” Being able to eat anything without gaining weight becomes a thing of the past. Fatty tissue increases, which leads to weight gain. Muscle strength decreases, and the reflexes slow. The leading cause of death in this age group is also unintentional injury, according to the CDC.²

FIGURE 9-11 An early adult.

© Rubberball Productions.

Psychosocial Changes

Three words best describe a human's world during this stage of life: work, family, and stress. During this period, humans strive to create a place for

YOU are the Provider

Part 3

After completing your assessment using the Pediatric Assessment Triangle (appearance, work of breathing, circulation), you determine the patient's level of consciousness is altered, her breathing is labored, and she is cyanotic. The mother states the infant has had a runny nose for the past couple of days and she has not had time to take her to the doctor. She states she was just overwhelmed caring for her sick daughter, a school-age child, and for her older adult mother who has dementia.

Recording Time: 4 Minutes

Respirations	32 breaths/min; labored
Pulse	Strong and regular; 130 beats/min
Skin	Warm, dry, and pink extremities; cyanosis around the lips and nose
Blood pressure	76/40 mm Hg
Oxygen saturation (SpO₂)	92% while breathing room air
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

- Are the patient's vital signs consistent with her age?
- Should you transport the patient to the hospital?

themselves in the world, and many do everything they can to settle down. As early adults struggle to find stability in their careers, stress on the job becomes high. Along with this natural tendency to settle down often comes marriage and family. Childbirth is most common in this age group. Despite all of this stress and change, this age group enjoys one of the more stable periods of life. People in early adulthood generally experience fewer psychological problems related to well-being.

Middle Adults (41 to 60 Years)

Physical Changes

A **middle adult** is 41 to 60 years of age (**FIGURE 9-12**). The average pulse rate for this age remains at 70 beats/min, the respiratory rate continues at 12 to 20 breaths/min, and the systolic blood pressure also remains between 90 and 140 mm Hg. Even though the body is still functioning at a high level, this age group is vulnerable to vision and hearing loss along with other varying degrees of degradation. Cardiovascular health becomes an issue in many people in this age group, as does the greater incidence of cancer. Middle adults may begin having medical symptoms or be unaware of conditions

FIGURE 9-12 A middle adult.

© Photodisc/Getty Images.

such as diabetes and hypertension. Medications or underlying conditions may affect a patient's response to treatments. In women, menopause—the cessation of menstruation—begins in the late 40s or early 50s. However, it is possible for an unexpected pregnancy to occur after experiencing menopause. Other concerns include an increase in cholesterol levels, a decrease in the efficiency of the heart, and weight control maintenance. However, many of the effects of aging can be diminished with exercise and a healthy diet. The CDC cites unintentional injuries as the leading cause of death of people ages 41 to 44 years. For ages 45 to 60 years, the leading cause of death is cancer.²

Psychosocial Changes

Middle adults tend to focus on achieving their life's goals, as they approach the halfway point in human life expectancy. After years of nurturing and living with children, parents must readjust their lifestyles as their children leave the home, commonly called the empty nest syndrome. Finances may become a worrisome issue as people prepare for retirement while still managing everyday financial demands. During this time, people often view crisis as a challenge to be overcome and not a threat to be avoided. Generally, their health is stable and they have the physical, emotional, and spiritual reserves to handle life's issues.

The parents of adults in this age group are getting older and now need care. Most of the older adults in the United States are cared for by family members inside the home. Therefore, a person in middle adulthood may need to manage children who are leaving for college while at the same time care for parents who require greater assistance.

Older Adults (61 Years and Older)

Physical Changes

The term **older adult** applies to people age 61 years or older (**FIGURE 9-13**). **Life expectancy** is constantly changing. In the early 1900s, life expectancy was 47 years. It is now approximately 78 years, with maximum life expectancy estimated at 120 years.³ The age to which a person will live is based on many factors. Perhaps not so surprisingly, the year you were born and the country you live in can affect

FIGURE 9-13 An older adult.

© Photodisc/Getty Images.

FIGURE 9-14 Older people are often prescribed multiple medications to help them stay active.

© Luis Alvarez/DigitalVision/Getty Images.

your life expectancy. These two facts are based on public health advances, changes within diets, attitudes regarding exercise, advances in medical care, access to that medical care, and personal behaviors. According to the CDC, heart disease and cancer are the leading causes of death in ages 65 years and older.²

Later in life, the vital signs depend on the patient's overall health, medical conditions, and medications taken. Today's older adults are staying active longer than their ancestors did. Thanks to medical advances, they are often able to overcome numerous medical conditions but may need multiple medications to do so (**FIGURE 9-14**).

Street Smarts

Some older patients have physical, cognitive, and psychological barriers that impede their ability to communicate effectively. Establish a baseline mental status, and never assume that confusion is normal in this population. Proper assessment and management will often depend on your ability to use patience and vary communication techniques when interviewing them.

Cardiovascular System

Cardiac function declines with age due to anatomic and physiologic changes that are largely related to atherosclerosis. Atherosclerosis most commonly affects coronary vessels. Cholesterol and calcium build up inside the walls of blood vessels, forming plaque. The accumulation of plaque eventually leads to partial or complete blockage of blood flow. Most people older than 65 years have some degree of atherosclerotic disease.⁴

Other age-related changes typically include a decrease in heart rate, a decline in cardiac output (the amount of blood circulated each minute), and the inability to elevate cardiac output to match the demands of the body. This translates into a heart that is less able to respond to exercise or disease (for example, by an increased heart rate). In the event of a life-threatening illness, the body typically needs to increase the heart rate to ensure adequate blood pressure. Because heart muscle may be weakened with age, the increase in heart rate can cause damage to the heart itself.

The vascular system also becomes stiff. Because of this change, the diastolic blood pressure increases with age. The left ventricle must then work harder to move blood effectively, so it becomes thicker, losing its elasticity in this process. There is increased workload of the heart and reduced blood flow to organs. Decreases in the amount of elastin and collagen in blood vessel walls reduce the elasticity of the peripheral vessels by as much as 70%. Compensation for blood pressure changes is hampered because the vessels are less able to dilate and contract.

Aging also affects blood cells. Blood cells originate from within the bone marrow. As a person ages, more of the bone marrow is replaced with

fatty tissue. This decrease in bone marrow causes a decrease in the ability of the bones to manufacture more blood cells when needed. While this change alone typically does not pose a problem, if an older adult sustains trauma, the ability of the body to produce blood cells to replace those lost decreases. Finally, functional blood volume gradually declines over time.

Respiratory System

In older adults, the size of the upper and lower airway increases as the smooth muscle weakens. The surface area of the alveoli decreases. These metabolic changes cause the natural elasticity of the lungs to decrease, forcing people to increasingly rely more on the muscle between their ribs, called intercostal muscle, to breathe. In addition, the chest becomes more rigid because of calcification of the ribs to the sternum, which adds to the difficulty of breathing. As the elasticity of the lungs decreases, the overall strength of the intercostal muscles and diaphragm also decreases. These factors together cause more labor-intensive breathing for older adults. You might think a rigid chest would be more protecting, but this rigidity makes the chest more fragile. Overall, the bone structure of older adults is weakened. Instead of the chest being able to bend and give if struck, the calcified bony structure of the chest can fracture. As with all physical changes related to aging, however, the changes in the respiratory system are often gradual and go unnoticed until a severe, life-threatening condition occurs. An older adult will then have less respiratory reserve to maintain adequate breathing.

Within the mouth and nose, there is a gradual loss of the mechanisms that protect the upper airway. This loss leads to decreased ability to clear secretions and decreased cough and gag reflexes. The number of cilia that line the airways diminishes with age, resulting in less sensation (and less responsiveness) when structures of the airway are irritated. With a lesser ability to maintain upper airway function, aspiration and obstruction become more likely.

When a younger patient inhales, the airway maintains its shape, allowing air to enter. As the smooth muscle of the lower airway weakens with age, strong inhalation can make the walls of the airway collapse inward and cause inspiratory

FIGURE 9-15 A. Healthy muscle in a younger patient's airway helps maintain the open airway during the pressures of inhalation. **B.** Muscle weakening with age can lead to airway collapse that may produce wheezing.

© Jones & Bartlett Learning.

wheezing (**FIGURE 9-15**). The collapsing airways result in low flow rates, because less air can move through the smaller airways, and air trapping, because air does not completely exit the alveoli (incomplete expiration).

Also within the airways, the cells of the immune system are less functional. As a result of the overall decrease in the metabolic activity of the older body, the white blood cells found within the airways are less aggressive at fighting invading organisms. This leads to an increased risk of lung infections.

By age 75 years, the vital capacity (the volume of air moved during the deepest inspiration and expiration) may amount to only 50% of the vital capacity noted in early adulthood. Factors that contribute to this decline include loss of respiratory muscle mass, increased stiffness of the thoracic cage, and decreased surface area available for the exchange of air.

Physiologically, vital capacity decreases and residual volume (the amount of air left in the lungs after expiration of the maximum possible amount of air) increases with age. Consequently, stagnant air remains in the alveoli and hampers gas exchange. This effect can produce hypercarbia (increased level of carbon dioxide in the bloodstream) and acidosis, even when the person is at rest.

Endocrine System

As with other systems of the body, the function of the endocrine system gradually declines with age. As people get older, they tend to slow their physical

activity. Unfortunately, many do not decrease their food intake. When a person gains weight, more insulin is needed to control the body's metabolism and blood glucose (sugar) level. However, insulin production and glucose metabolism decrease with age, so older adults are more susceptible to diabetes mellitus. Changes in older adults' mental status may also be the result of changes in their blood glucose level.

The male and female reproductive systems also change with age. Men are able to produce sperm long into their 80s but the rigidity of the penis tends to decrease over time. It is unclear whether this decrease is solely due to aging or other factors such as cardiovascular disease. During menopause, decreased production of regulating hormones results in atrophy of the woman's reproductive organs. The uterus and vagina both decrease in size. Hormone production for both sexes gradually decreases as people age. Sexual desire may diminish with age but does not cease.

Special Populations

Always monitor blood glucose levels in older adult patients presenting with altered mental status. Remember, the symptoms of hypoglycemia can mimic those observed in stroke (for example, facial drooping and hemiparesis).

Renal and Gastrointestinal Systems

In the kidneys, both structural and functional changes occur in older adults. The filtration function of these organs, for example, declines by 50% from age 20 to 90 years. Kidney size decreases by 20% over the same span. This is due in part to the decreased effectiveness of the blood vessels that supply blood to the nephrons. **Nephrons** are sophisticated capillaries that perform filtering in the kidney. They are the structural and functional units of the kidney that form urine. One of the portions of the nephron is the *glomerulus*. The decreased blood supply causes more abnormal glomeruli to be present as a person ages. The number of nephrons also declines between the ages of 30 and 80 years. The loss of renal function means a decrease in the ability to clear wastes from the body. It also means decreased ability to conserve fluids when needed.

Changes in gastrointestinal function may inhibit nutritional intake and utilization in older adults, resulting in vitamin and mineral deficiencies. In the mouth, for example, taste bud sensitivity to salty and sweet sensations decreases. The sense of smell can also be diminished and, along with the decreased taste response, can diminish the flavor of food. Teeth become weaker during this phase of life, making it more difficult for older adults to chew certain foods. The secretion of saliva decreases, which reduces the

YOU are the Provider

Part 4

You suction the infant's nose with a bulb syringe and your partner administers blow-by oxygen. You explain your findings to the mother and inform her the infant needs to be transported to the hospital for further treatment. The mother calls a neighbor to stay with her older child and her mother. While your partner secures the infant in a child safety seat, you take a moment to speak with the woman about the options available to help her care for her aging mother.

Recording Time: 8 Minutes

Respirations	28 breaths/min; not as labored
Pulse	Strong and regular; 120 beats/min
Skin	Warm, dry, and pink extremities, decreased cyanosis around lips and nose
Blood pressure	76/60 mm Hg
Oxygen saturation (SpO₂)	95% on blow-by oxygen
Pupils	PERRLA

7. What other options could you offer the mother?

body's ability to process complex carbohydrates. Gastric motility slows with age because of the loss of intestinal tract neurons, which can lead older adults to feel constipated or not hungry. Likewise, the secretion of gastric acid diminishes. Blood flow in the mesenteric vessels (supplying membranes that connect organs to the abdominal wall) may drop by as much as 50%, decreasing the ability of the intestines to extract nutrients from digested food. Gallstones become increasingly common with age, and anal sphincter changes reduce elasticity and can produce fecal incontinence.

Nervous System

Nervous system changes can result in the most debilitating of age-related ailments. In the central nervous system, the brain weight may decrease 10% to 20% by age 80. Motor and sensory neural networks become slower and less responsive. The metabolic rate in the older brain does not change, however, and oxygen consumption remains constant throughout life. Generally, you have fewer brain cells (neurons) today than you did yesterday. If measured strictly by numbers of brain cells, infants are far more intelligent than any of us. However, this is not how the brain works. Although it is true that older adults have a diminished number of brain cells, there is great flexibility in the operation of the brain. Interconnections between brain cells continue as people age. These new connections provide redundancy within the brain, allowing for loss of neurons without loss of knowledge or skill.

One of the consequences of the loss of neurons is a change in the sleep patterns of older adults. Instead of sleeping through the night, they may take a nap during the day and be up late at night. Their sleep cycle may move into a biphasic (two-phased) sleep cycle—for example, sleep from 0100 hours to 0600 hours and nap from 1200 hours to 1500 hours.

The brain, which is surrounded by the meninges, takes up almost all of the space in the skull. Cerebrospinal fluid protects the brain inside these membranes. Unfortunately, in older adults, age-related shrinkage creates a void between the brain and the outermost layer of the meninges, which provides room for the brain to move when stressed (**FIGURE 9-16**). If trauma moves the brain forcibly, the bridging veins can tear and bleed.

FIGURE 9-16 Age-related atrophy or shrinkage of the brain results in a space between the brain and its cover, the dura mater. Bleeding into this area can occur more easily from trauma because veins are stretched. Because of the additional space, bleeding in an older brain does not always produce immediate signs of increased intracranial pressure.

© Jones and Bartlett Learning.

Bleeding can empty into this void and may go unnoticed for some time in this age group.

Functioning of the peripheral nervous system also slows with age. Sensation becomes diminished and misinterpreted. The ability to know where the body is in space (proprioception) can be diminished. Slower reaction times cause longer delays between stimulation and motion. The slowdown in reflexes and decreased kinesthetic sense may contribute to the incidence of falls and trauma. Nerve endings deteriorate, and the ability of the skin to sense the surroundings becomes hindered. Hot, cold, sharp, and wet items can all create dangerous situations because reaction time and pain perception are both diminished in older adults.

Sensory Changes

In addition to a diminished sensation of touch, the other senses are also affected by aging. It is often assumed older adults are hard of hearing and have difficulty seeing. While it is true that there are changes that diminish the effectiveness of the eyes and ears, most older adults hear well and have good vision. They may need eyeglasses or hearing aids, but do not assume your older patient is deaf and nearly blind. Pupillary reaction and ocular movements become more restricted with age. The pupils are generally smaller in older patients, and the opacity of the eye's lens diminishes visual acuity and makes the pupils sluggish when responding to light. Visual distortions are also common in older people. Thickening of the lens makes it more difficult for the eye to focus, especially at close range. Peripheral fields of vision become narrower, and a greater sensitivity to glare constricts the visual field.

Hearing loss is about four times more common than loss of vision in older adults. Changes in several hearing-related structures may lead to a loss of high-frequency hearing or even deafness.

Psychosocial Changes

You should treasure the opportunities to spend time with and communicate with older adults. Many older adults have amazing stories and experiences to share, yet we often take them for granted. They share a great amount of wisdom with us, and we need to remind them of their self-worth. Until about 5 years before death, most late-stage adults retain high brain function. In the 5 years preceding death, however, mental function is presumed to decline, a theory referred to as the **terminal drop hypothesis**.

As the older adult population continues to grow, we have the responsibility to seek unique ways to accommodate their needs during their last 20 to 40 years of life. The increasing number of older adults in the United States as a result of the baby boom of the 1940s through the 1960s has produced a need for more assisted-living facilities. These facilities allow older adults to live in campus-based communities with people in their own age group, while enjoying the privacy of their own apartments and the security of nursing care, maintenance, and food preparation, if desired (**FIGURE 9-17**). Unfortunately, congregate living facilities are ideal environments

for the spread of infectious diseases such as influenza and COVID-19. Disease transmission in these environments may be particularly problematic during times of pandemic illness. These facilities also tend to be expensive.

Most people need to deal with financial issues throughout their lives. Few things in life produce more worry and stress than money problems. In particular, older adults may constantly worry about the rising costs of health care and are often forced to make decisions such as whether to pay for groceries or their medication. Compared with earlier generations, families often take less responsibility for their older adult family members. According to the US government, 9.3% of people age 65 years and older (4.6 million) were below the poverty level in 2016. This problem continues.⁵

One of the important issues that older adults face is mortality. However, the fact is, everyone dies. Yet, for most of us, this concept is an intellectual exercise with a distant connection to reality. It is difficult for older adults to watch as their friends, relatives, and companions grow older and die, leaving them seemingly alone. Older adults may feel useless or worry about being a burden to their families as their health declines and they are no longer able to take care of themselves. Isolation and depression are challenges for older adults.

Fortunately, many older adults are happy and actively participating in life. With good financial resources and a good support system of family and friends, older adults in their 80s and beyond can enjoy life and continue to feel productive.

FIGURE 9-17 An increasing number of older adults live in assisted-living facilities.

YOU are the Provider SUMMARY**1. How does the patient's age affect your treatment?**

The caregiver will be your primary resource for determining the patient's normal mental status and activity level. The 3-month-old infant should be able to track objects with her eyes and should recognize familiar faces. The development of stranger anxiety does not occur until age 1 year or older.

2. What are some physical differences between pediatric and adult patients?

Compared with an adult, the infant has a proportionately larger tongue and proportionately shorter, narrower, and less stable airway. As a result, the airway in infants can be occluded easily. Infants have fewer alveoli in their lungs, which decreases the surface area for gas exchange. They also continue to be nose breathers and have not mastered the ability to breathe through their mouths. The rib cage of an infant is less rigid than an adult's, and the ribs sit horizontally. This explains the diaphragmatic breathing in infants. Owing to the immaturity of the accessory muscles, fatigue sets in quickly.

3. Why are the secretions around the infant's nares significant?

Neonates are primarily nose breathers for the first 4 weeks of their lives, but even older infants rely heavily on nose breathing for ease during feeding. Something as simple as nasal congestion can lead to hypoxia in the infant. Infants younger than 6 months are particularly susceptible to nasal congestion, which can cause viral upper respiratory infections. If you receive a call for an infant choking, ensure the nasal passages are clear and unobstructed by mucus.

4. What are some common psychosocial concerns experienced by pediatric patients?

Infants communicate primarily by crying. Parents can often tell what is upsetting the infant by listening to the tone of the child's crying. Infants occasionally make another distinct cry—an alarming distressed cry. This cry may be heard when an unexpected event occurs, causing a situational crisis for the infant. Because this infant is lethargic and responds only when stimulated, she may be more difficult to evaluate.

5. Are the patient's vital signs consistent with her age?

In infants (1 month to 1 year), the pulse rate is 90 to 180 beats/min and the respiratory rate is 30 to 53 breaths/min. The systolic blood pressure is 72 to 104 mm Hg, so these findings are consistent for the age of the patient.

6. Should you transport the patient to the hospital?

In this scenario, transport is recommended due to the respiratory distress and change in level of consciousness.

7. What other options could you offer the mother?

The mother is feeling overwhelmed because she is caring for three different age groups all needing individual attention. You could suggest possible options for the older child such as an afterschool program or other adult-led activities. You may also inform the mother of potential resources available in the community to assist in caring for her mother.

YOU are the Provider **SUMMARY** *continued***EMS Patient Care Report (PCR)**

Date: 6-27-21	Incident No.: 20102291036	Nature of Call: Runny nose		Location: 26445 NE Dresser Rd	
Dispatched: 1504	En Route: 1505	At Scene: 1512	Transport: 1517	At Hospital: 1523	In Service: 1530

Patient Information

Age: 3 months
Sex: F
Weight (in kg [lb]): 7 kg (16 lb)

Allergies: No known drug allergies
Medications: None
Past Medical History: None
Chief Complaint: Runny, sore nose

Vital Signs

Time: 1516	BP: 76/40	Pulse: 130	Respirations: 32	Spo₂: 92%
Time: 1520	BP: 76/60	Pulse: 120	Respirations: 28	Spo₂: 95%

Assisted Ventilation**Airway Adjunct****CPR****Defibrillation****Bleeding Control****Bandaging****Splinting****Other:****Narrative**

EMS dispatched to above location for a runny nose. On arrival, met by mother who is holding a 3-month-old infant in her arms. Mother states the patient has had a runny nose for a couple of days and is now less responsive. Physical exam reveals a lethargic infant who responds sluggishly to tactile stimulation. The infant presents with cyanosis around her nose and lips and has yellow drainage from both nares. Nares are suctioned with a bulb syringe and infant is placed on blow-by oxygen at 6 L/min. Advised mother of our findings, and she agreed to transport. The patient was secured in child safety seat and seat was secured in the ambulance. After suctioning and the administration of oxygen, infant is more alert. Patient and mother transported to hospital without incident. Older child and patient's grandmother left in care of neighbor. Mother advised of outreach resources available to assist in caring for her mother. EMS back in service at 1530.

End of report

Prep Kit

Ready for Review

- Developmental stages of life include the following: neonate, infant, toddler, preschool age, school age, adolescence, early adulthood, middle adulthood, and older adulthood.
- Each developmental stage is marked by different physical and psychosocial changes and characteristics.
- The pulse rate is fastest during infancy, ranging from 100 to 205 beats/min. This rate slows and levels off during adolescence, reaching the adult range of 60 to 100 beats/min.
- The typical respiratory rate is highest in neonates, at 30 to 60 breaths/min. The respiratory rate levels off during adolescence, reaching the adult range of 12 to 20 breaths/min.
- Blood pressure directly corresponds to the patient's weight, so it typically increases with age. In a neonate, the systolic blood pressure ranges from 67 to 84 mm Hg, while in adults (early, middle, and older) it ranges from 90 to 140 mm Hg.
- By 2 weeks, neonates and infants grow at a rate of about 1 ounce (30 g) per day, doubling their weight within 4 to 6 months and tripling it by the end of the first year.
- Two important points regarding an infant's airway are that an infant's tongue can more easily occlude the airway, and the lungs are fragile. Ventilations that are too forceful can result in barotrauma.
- Toddlers (1 to 3 years) and preschoolers (3 to 6 years) continue to learn to speak and express themselves. Toilet training is usually accomplished around age 28 months.
- School-age children (6 to 12 years) develop self-esteem and reasoning abilities and receive their permanent teeth.
- Adolescents (12 to 18 years) undergo significant reproductive development. They also focus on creating their self-image and are self-conscious. They may also engage in self-destructive behavior such as smoking, drinking alcohol, or taking drugs.
- Early adults (19 to 40 years) focus on work and family. The body should function at an optimal level, and lifelong habits are developed.
- Middle adults (41 to 60 years) focus on achieving life goals. During this stage, medical conditions such as diabetes, hypertension, and cancer become more common.
- While many older adults (61 years and older) are happy and actively participating in life, some focus on their mortality and the mortality of friends and loved ones.
- The vital signs of older adults depend on their health.
- There are significant physical changes in older adults. Cardiac function declines as atherosclerosis develops. Cardiac output decreases, and the vascular system becomes stiff.
- Respiratory changes in older adults include decreased elasticity of the lungs, decreased vital capacity and residual volume, and decreased ability to clear secretions.
- Bones become more rigid in late adulthood, making them more susceptible to fracture.
- Endocrine changes in older adults include decreases in insulin production and glucose metabolism.
- Renal changes in older adults include decreases in filtration function.
- Gastrointestinal changes in older adults include decreased saliva, slowed gastric motility, and potentially incontinence.

- Nervous system changes affect sleep patterns in older adults and increase the likelihood of falls.
- Age-related shrinkage creates a void that forms between the brain and the outermost layer

of meninges. As a result, bleeding may go unnoticed for some time.

- Sensory changes associated with aging include hearing loss and vision problems; however, many older adults hear and see relatively well.

Vital Vocabulary

adolescent A young person age 12 to 18 years.

anxious-avoidant attachment An insecure attachment observed in infants who are repeatedly rejected. Children develop an isolated lifestyle that does not depend on the support and care of others.

bonding The formation of a close, personal relationship.

conventional reasoning A type of reasoning in which a child looks for approval from peers and society.

early adult A young adult age 19 to 40 years.

fontanelles Areas where the neonate's or infant's skull bones have not fused together; usually disappear at approximately 18 months of age.

growth plates Structures located on either end of an infant's long bone, which aid in lengthening bones as the child grows; also known as epiphyseal plates.

infant A young child age 1 month to 1 year.

life expectancy The average number of years a person can be expected to live.

middle adult An adult age 41 to 60 years.

Moro reflex An infant reflex in which, when an infant is caught off guard, the infant opens the arms wide, spreads the fingers, and seems to grab at things.

neonate A newborn age birth to 1 month.

nephrons The structural and functional units of the kidney that form urine; composed of the glomerulus, the glomerular (Bowman) capsule, the proximal convoluted tubule, loop of Henle, and the distal convoluted tubule.

older adult An adult age 61 years or older.

palmar grasp An infant reflex that occurs when something is placed in the infant's palm; the infant grasps the object.

postconventional reasoning A type of reasoning in which a child bases decisions on their conscience.

preconventional reasoning A type of reasoning in which a child acts almost purely to avoid punishment or to get what the child wants.

preschooler A child age 3 to 6 years.

rooting reflex An infant reflex that occurs when something touches an infant's cheek; the infant instinctively turns the head toward the touch.

school age A child age 6 to 12 years.

secure attachment A bond between an infant and a parent or caregiver in which the infant understands that the parents or caregivers will be responsive to the infant's needs.

separation anxiety An infant behavior that peaks between 10 to 18 months. The child may exhibit clingy behavior and fear of unfamiliar places and people.

sucking reflex An infant reflex in which the infant starts sucking when the lips are stroked.

terminal drop hypothesis A theory that a person's mental function declines in the last 5 years preceding death.

toddler A child between 1 and 3 years of age.

trust and mistrust Refers to a stage of development from birth to approximately 18 months of age, when infants gain trust of their parents or caregivers if their world is planned, organized, and routine.

Patient Assessment

10 Patient Assessment

SECTION

3

Chapter 10

Patient Assessment

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Assessment

Applies scene information and patient assessment findings (scene size-up, primary and secondary assessment, patient history, reassessment) to guide emergency management.

Scene Size-up

- Scene safety (pp 461–462)
- Scene management (pp 460–461)
 - Impact of the environment on patient care (p 460)
 - Addressing hazards (pp 461–462)
 - Violence (pp 461–462)
 - Need for additional or specialized resources (pp 466–467)
 - Standard precautions (pp 464–465)
 - Multiple patient situations (pp 465–466)

Primary Assessment

- Primary assessment for all patient situations
 - Level of consciousness (pp 470–472)
 - ABCs (p 481)
 - Identifying life threats (p 485)
 - Assessment of vital functions (p 468)
 - Initial general impression (pp 469–470)
- Begin interventions needed to preserve life (p 485)
- Integration of treatment/procedures needed to preserve life (p 485)

History Taking

- Determining the chief complaint (pp 489–491)
- Mechanism of injury/nature of illness (pp 462–464)

- Associated signs and symptoms (p 494)
- Investigation of the chief complaint (p 489)
- Past medical history (pp 494–495)
- Pertinent negatives (p 494)

Secondary Assessment

- Performing a rapid full-body scan (p 502)
- Focused assessment of pain (pp 506, 512)
- Assessment of vital signs (pp 502–504)
- Techniques of physical examination
 - Respiratory system (p 512)
 - Presence of breath sounds (p 474)
 - Cardiovascular system (p 517)
 - Neurologic system (pp 522–524)
 - Musculoskeletal system (p 527)
 - All anatomic regions (pp 524–525)
- Assessment of
 - Lung sounds (p 474)

Monitoring Devices

- Obtaining and using information from patient monitoring devices including (but not limited to)
 - Pulse oximetry (p 503)
 - Noninvasive blood pressure (pp 503–504)
 - Blood glucose determination (p 506)

Reassessment

- How and when to reassess patients (p 530)
- How and when to perform a reassessment for all patient situations (p 531)

KNOWLEDGE OBJECTIVES

1. Identify the components of the patient assessment process. (p 455)
2. Explain how the different causes and presentations of emergencies will affect how you perform each step of the patient assessment process. (pp 455–457)
3. Describe the key elements of the critical thinking process and how you can apply them in the field. (pp 457–461)
4. Discuss some of the possible environmental, chemical, and biologic hazards that may be present at an emergency scene, ways to recognize them, and precautions to protect personal safety. (p 461)
5. Discuss how to survey a scene for signs of violence and protect yourself and bystanders from real or potential danger. (pp 461–462)
6. Describe how to determine the mechanism of injury or nature of illness at an emergency and the importance of differentiating trauma patients from medical patients. (pp 463–464)
7. List the minimum standard precautions that should be followed and personal protective equipment that should be worn at an emergency scene, including examples of when additional precautions would be appropriate. (pp 464–465)
8. Explain why it is important to identify the total number of patients at an emergency scene and how this evaluation relates to determining the need for additional or specialized resources, implementation of the incident command system, and triage. (pp 465–467)
9. Describe the principal goals of the primary survey process. (pp 468–469)
10. Explain the process of forming a general impression of a patient as part of the primary survey and the reasons why this step is critical to patient management. (pp 469–470)
11. Describe the assessment of airway status in patients who are responsive and unresponsive. (pp 471–472)
12. Give examples of possible signs and causes of airway obstruction in patients who are responsive and unresponsive, as well as the appropriate response. (pp 472–473)
13. Describe the assessment of a patient's breathing status, including the key information you must obtain during this process and the emergency medical care required for patients who have both adequate and inadequate breathing. (p 474)
14. List the signs of respiratory distress and respiratory failure. (pp 475–476)
15. Describe the assessment of a patient's circulatory status, including the different methods for obtaining a pulse and appropriate management depending on the patient's status. (p 476)
16. Explain the variations required to obtain a pulse in infant and child patients compared with adult patients. (pp 476–478)
17. Describe the assessment of a patient's skin color, temperature, and condition, including examples of both normal and abnormal findings and the information this provides related to the patient's status. (pp 478–479)
18. Discuss the process of assessing for and methods for controlling external bleeding. (p 480)
19. Explain the importance of assessing a patient's level of consciousness to determine altered mental status. (pp 470–472)
20. Give examples of different methods used to assess alertness, responsiveness, and orientation. (p 481)
21. List the steps to follow during the primary survey of a trauma patient, including examples of abnormal signs and appropriate related actions. (pp 483–484)
22. Discuss the steps used to identify and subsequently treat life-threatening conditions that endanger a patient during an emergency. (p 485)
23. Explain the process for determining the priority of patient care and transport at an emergency scene, including examples of conditions that necessitate rapid transport. (pp 485–488)
24. Discuss the importance of protecting a trauma patient's spine and identifying fractured extremities during patient packaging for transport. (p 486)
25. Discuss the process of taking a patient history, its key components, and its relationship to the primary survey process. (p 489)
26. Describe examples of different techniques you may use to obtain information from patients during the history-taking process. (pp 489–497)
27. Discuss different challenges you may face when taking a patient history on sensitive

- topics and strategies that can be used to facilitate each situation. (pp 497–501)
28. Describe the purpose of performing a physical exam during secondary assessment, its components, special patient considerations, and methods for determining which aspects of the physical exam will be used. (pp 502–503)
 29. Name the devices used to monitor a patient's medical condition during the secondary assessment and reassessment. (pp 503–506)
 30. Describe the purpose of a full-body exam, and list the steps used during this process. (pp 506–511)
 31. Explain situations in which patients may receive a focused assessment, including examples, by body system, of what each focused assessment should include based on a patient's chief complaint. (pp 506, 512)
 32. List normal respiratory rate, pulse rate, and blood pressure ranges for adults, children, and infants. (p 514)
 33. Explain the importance of performing a reassessment of the patient and the steps in this process. (pp 530–531)

SKILLS OBJECTIVES

1. Demonstrate the techniques for assessing a patient's airway, and correctly obtain information related to respiratory rate, rhythm, quality/character of breathing, and depth of breathing. (p 469)
2. Demonstrate how to obtain a pulse rate in a patient. (p 477)
3. Demonstrate how to assess a radial pulse in a responsive patient and an unresponsive patient. (p 477)
4. Demonstrate how to assess a carotid pulse in an unresponsive patient. (p 477)
5. Demonstrate how to palpate a brachial pulse in a child who is younger than 1 year (or a manikin). (p 477)
6. Demonstrate how to assess capillary refill in an adult or child older than 6 years. (p 480)
7. Demonstrate how to assess capillary refill in an infant or child younger than 6 years. (p 480)
8. Demonstrate how to use the AVPU scale to test for patient responsiveness. (p 471)
9. Demonstrate how to evaluate a patient's orientation and document the patient's status correctly. (p 457)
10. Demonstrate how to perform a rapid full-body scan during the primary survey of a patient. (pp 483–484, Skill Drill 10-1)
11. Demonstrate the use of a pulse oximetry device to evaluate the effectiveness of oxygenation in the patient. (p 503)
12. Demonstrate the use of electronic and manual devices to assist in determining the patient's blood pressure in the field. (pp 504–505)
13. Demonstrate the use of an end-tidal carbon dioxide monitoring device to assist in determining the patient's concentration of expired carbon dioxide in the field. (pp 504–505)
14. Demonstrate how to assess a patient's blood glucose level. (p 507, Skill Drill 10-2)
15. Demonstrate how to perform a full-body exam. (pp 508–511, Skill Drill 10-3)
16. Demonstrate how to perform a focused assessment. (p 512)
17. Demonstrate how to measure blood pressure by auscultation. (p 520, Skill Drill 10-4)
18. Demonstrate how to measure blood pressure by palpation. (p 521, Skill Drill 10-5)
19. Demonstrate how to test pupil reaction in response to light in a patient and document their status correctly. (p 523)

Introduction

The importance of patient assessment cannot be overemphasized. As an emergency medical services (EMS) provider, you must master and be comfortable with the patient assessment process. Patient assessment is used, to some degree, in every patient encounter. You will develop and perfect your own assessment techniques as you complete your education and gain field experience. It is also important to understand the processes of thinking and decision making. By having a better understanding of how your thoughts are formed and processed, you can learn to think more effectively.

The assessment process is divided into five main parts:

1. Scene size-up
2. Primary survey
3. History taking
4. Secondary assessment
5. Reassessment

The five steps of the patient assessment process represent a logical approach to the evaluation of a patient, but the order in which you perform them is determined by the patient's condition and the environment in which you find the person. The same components of patient assessment used to evaluate a medical patient are used to assess a

trauma patient; the differences lie in your findings and how you effectively care for your patient. Whether you are assessing a medical patient or a trauma patient, the key in both situations is to remain organized.

A **sign** is an objective condition that you can observe (see, hear, feel, smell, or measure) about the patient. A **symptom** is a subjective condition that the patient feels and tells you about. Rarely does one sign or symptom definitively disclose to you the patient's status or underlying problem (**FIGURE 10-1**). Rather, it is the combination of many signs and symptoms that reveals the underlying problem or condition of your patient. Therefore, it is essential to have a basic understanding of the causes and presentations of emergencies so that you know what to look for.

For example, consider a patient who has crushing chest pain radiating down the left arm and jaw (a symptom) and is diaphoretic and pale (signs). If the onset of his symptoms occurred while he was shoveling snow and his past medical history includes coronary bypass surgery, then you are more likely to suspect and treat myocardial infarction (MI) than other conditions with the same **chief complaint** (the reason EMS was called). In this example, you can see how it is essential to collect all pertinent information and be able to interpret how the pieces of information fit together.

YOU are the Provider

Part 1

Your EMS crew is dispatched to a motor vehicle crash (MVC). As you are responding, dispatch advises you that law enforcement personnel are already on scene with a one-vehicle crash, sedan versus tree, at an estimated 35 mph. Dispatch also advises you that the patient is unresponsive.

1. What are the components of a scene size-up?
2. What can you do to ensure scene safety?

Patient Assessment

Scene Size-up

Ensure scene safety
Determine mechanism of injury/nature of illness
Take standard precautions
Determine number of patients
Consider additional/specialized resources

Primary Survey*

Form a general impression

Assess

- Responsiveness/level of consciousness

Assess and Treat

- Exsanguinating hemorrhage
- Airway
- Breathing
- Circulation

Also Assess

- Disability
- Exposure

Identify

- Chief complaint/life threats (treat)
- Priority of patient care
- Transport decision

History Taking

Investigate

- Chief complaint
- History of present illness (OPQRST)
- Past medical history (SAMPLE)

Secondary Assessment

Is the patient medical or trauma?

Assess

- Baseline vital signs
- Monitoring devices (as appropriate)

Systematic physical exam

- Full-body exam or rapid full-body scan
- Focused on injury
- Based on body system (respiratory, cardiovascular, neurologic, reproductive, etc)

Reassessment

- Repeat the primary survey
- Reassess vital signs
- Reassess the chief complaint
- Recheck interventions
- Identify and treat changes in the patient's condition

Reassess patient

- Unstable patients: every 5 minutes
- Stable patients: every 15 minutes

***Note:** The primary survey usually follows an ABCDE sequence (Airway, Breathing, Circulation, Disability, Exposure) or XABCDE in trauma patients (where X stands for eXsanguinating hemorrhage), but if the patient appears lifeless or has severe external bleeding, use a CABDE sequence (Circulation, Airway, Breathing, Disability, Exposure).

A

B

FIGURE 10-1 **A.** A symptom is a subjective condition that the patient feels and tells you about. **B.** A sign is an objective condition that you can observe about the patient.

This chapter provides the framework and information necessary for you to understand the fundamental elements that contribute to the critical

thinking and decision-making processes, as well as how to conduct the patient assessment process. The patient assessment process is the ground on which all levels of EMS education are built and is the foundation of all emergency medical care. As an advanced emergency medical technician (AEMT), you cannot effectively treat your patients if you cannot correctly assess them. Strong critical thinking and assessment skills will assist you in the process of saving lives.

Clinical Decision Making and Critical Thinking

Effective clinical decision making is dependent on your ability to gather, evaluate, and synthesize patient information; develop an idea of the patient's problem based on gathered information and the patient's presentation; and formulate a field impression on which an appropriate patient treatment plan will be based. This process is called critical thinking.

Gathering, evaluating, and correctly synthesizing patient information will culminate in an appropriate treatment plan. This process requires an understanding of the patient's injury or illness and the impact that your emergency medical care will have on it. You will develop needed critical thinking skills through field experience in dealing with multiple patients with varying problems. In every assessment you perform, practice the following critical thinking skills:

- **Gathering information.** Ensure you have an adequate fund of knowledge and facts. The prehospital setting may be one of controlled chaos; your sources of information may be overwhelming or severely limited. Observe the scene and question the patient and bystanders. Use your knowledge and understanding of anatomy, physiology, pathophysiology, and how injuries and illnesses might or will affect the patient. Knowledge is acquired from initial training, continuing education, and experiences.
- **Evaluating information.** Consider the meaning of the gathered information. Multiple amounts of specific, crucial data, often from multiple sources, must be obtained to direct your assessment and subsequent treatment.

Street Smarts

People call 9-1-1 during some of the most difficult times of their lives. In some cases, they call because of a serious illness or injury. In others, they call because the patient or family is frightened, overwhelmed, or unable to cope with a problem any longer. The patient is often fatigued, sick, frightened, angry, or sad, and the family often shares some or all of these feelings. Regardless of the exact nature of the call, the patient, family, and bystanders expect you to bring comfort, control, and resolution of these problems—emotional and physical.

In many ways, good communication skills are as important as technical proficiency, if not more so. Each step in the assessment process can be impeded by inadequate communication, and each can be enhanced by a good connection between you and the patient and family. Here are five tips that can vastly improve your communication skills during the assessment process:

1. Quickly do whatever you can to make yourself and the patient comfortable. When time permits, sit down and/or position yourself near the patient, introduce yourself, and ask the patient's name. These simple actions signal to the patient that you have time to talk; they open the channels of communication as nothing else will.
2. Actively listen to the patient. In many cases, patients will be able to tell you what is wrong if you are paying attention and truly listening. You can use several skills to actively listen, including leaning in toward the patient, taking selective notes, and periodically repeating back important points to the patient to ensure you understood correctly. Active listening also involves asking follow-up questions related to the information the patient gives you.
3. Make eye contact with the patient. Eye contact signals that you are listening, so the patient is

more likely to open up. An added benefit is that you will see facial expressions that, in some cases, communicate information more clearly than the patient's words.

4. Base your initial questions on the patient's complaints. No one likes to think that they are "just another patient," but that idea is what you communicate if you always ask the same questions of every patient, regardless of the complaint. Talk about the patient's problem first; obtain demographic information after tending to the patient's needs.
5. Before you start treatment, stop for a moment and mentally summarize what you have learned and what you are going to do; then tell the patient. By providing necessary information to the patient and family, you help to relieve their anxiety and fear. This practice will also give them an opportunity to give you additional information if you have missed something.

Make it a point to spend your entire EMS career fine-tuning your patient assessment skills, because they are the cornerstone of high-quality prehospital care. An inadequate assessment almost always results in substandard patient care. Therefore, approach each patient with the same thorough assessment. Unless you take a systematic approach to patient assessment, you will systematically fail to find and treat life threats.

Be sure to focus some of your energy on improving the communication process. You will make it easier for patients to feel comfortable around you, which will help them to give honest, direct answers to your questions. As a result, you will get better assessment information in less time. See Chapter 4, *Communications and Documentation*, for a detailed look at communicating with patients.

You must be able to prioritize this information in a short time, separate relevant from irrelevant data, and provide the most appropriate emergency medical care for the patient. Irrelevant or extraneous data can skew your interpretation of the overall situation, potentially leading to inappropriate patient care. Analyze and compare similar situations from your own experiences.

- **Synthesizing information.** Put together the data you have gathered and evaluated, and

then form a plan to manage the scene and/or patient. Your overall understanding of the situation and the treatment that you provide to the patient are only as good as the quality and quantity of data that you obtain.

Although no two patients present in the exact same manner, you must be able to integrate the information you obtain regarding the current incident with similar situations and experiences. This integration will enhance your overall understanding of the current situation and will prepare

you to deal with future situations. Recall difficult situations. Recalling and learning from bad experiences enhances your ability to manage the current

Words of Wisdom

Sometimes you will need to think outside the box and do something in a manner inconsistent with guidelines. For example, you may need to use a Kendrick Extrication Device (KED) to remove an unstable patient from entrapment due to space constraints. Under normal circumstances, a KED should only be used on stable patients complaining of neck or back pain. If you do not follow proper procedure because you are acting in the best interest of the patient, then clearly document what you did and the reason for doing it.

situation. Articulate assessment-based decisions and construct arguments. You must be able to defend your actions and justify the decisions on which you based your treatment.

The performance of your duties will constantly be challenged by the environment in which you function. Time is perhaps your biggest challenge, especially when managing a critically ill or injured patient. Factors that can hamper your ability to perform emergency medical care—crowds of people, volatile scenes, poor lighting, weather extremes, bumpy ambulances—usually do not exist in other medical settings. Your ability to improvise, adapt, and overcome these unique obstacles—and still provide appropriate emergency medical care—will make you an effective clinical decision maker and a true prehospital professional. Always base your treatment or transport decisions on your assessment of the patient, discussed next.

Words of Wisdom

The fundamental elements that contribute to the critical thinking and clinical decision-making processes are listed below. As you look over each item on the following list, ask yourself, “Do I have this quality already, or do I need to develop it?”

- Adequate knowledge of anatomy, physiology, and pathophysiology
- Ability to gather and organize data and form concepts
- Ability to focus on specific and multiple elements of data
- Ability to identify and deal with **medical ambiguity**—uncertainty regarding the specific cause of the patient’s condition. Few 9-1-1 calls follow the scripts in your protocols to the letter.
- Skill in differentiating between relevant and irrelevant data
- Ability to analyze and compare similar and contrary situations
- Ability to articulate your reasoning and construct arguments

Patient Assessment

Scene Size-up

The **scene size-up** refers to your evaluation of the conditions in which you will be operating; it is the information gathering stage of the patient assessment process. Although the scene size-up should be the focus of your attention when you first arrive on scene, a continuous **situational awareness** is necessary throughout the entire call to ensure safety. Situational awareness is paying attention to the conditions and people around you at all times and understanding the potential safety risks those conditions or people pose.

For example, before you know the exact location of an incident, consider the environmental conditions. Is it cold, snowing, raining, dark, hot, or

humid? Consider how the weather may affect the physical terrain you may encounter. Even relatively mild weather conditions may present a significant hazard if responders and patients are exposed for a significant amount of time.

You must begin to prepare for a specific situation based on the initial dispatch information. From the moment you are called into action until you reach your patient, you must consider a variety of factors that will have an impact on how you operate on the scene and provide patient care. These factors include road and traffic hazards (which may affect where you park your emergency vehicle) and incident hazards such as fire, hazardous materials (hazmat), or scenes of violence (which may affect if and how you approach the scene). To help ensure

safe and effective operations, your scene size-up must combine an understanding of the situation based on the information the dispatcher provides with your observation of the scene itself. Your observation of the scene will help you to identify hazards, safety concerns, the number of patients, and the need for additional resources required to safely and effectively care for the patient.

Safety

Assessing the safety of a scene before entering is the single most important way in which you can attend to your own well-being. Subtle signs of danger that are not recognized and neutralized—or avoided—at this point can quickly become more threatening after you shift your attention to patient assessment and emergency medical care. Remember that scenes are dynamic (constantly changing), so maintain your situational awareness.

Ensure Scene Safety

The prehospital setting is not a controlled and isolated scene; it is unpredictable, dangerous, and unforgiving. What seems relatively safe and secure can change without notice. Every prehospital scene has a potential for injury and, if you or your partner becomes injured or incapacitated so that you cannot function at the emergency, you have taken away the initial resource to care for the patient. You need to ensure safety for you and your partner first, other responders and bystanders second, and your patient last.

As mentioned previously, dispatch information helps you to anticipate potential hazards prior to arriving on scene. For example, an MVC on a busy roadway indicates, at a minimum, that you must wear a high-visibility Class 2 or Class 3 safety vest approved by the American National Standards Institute. A safety vest helps make you visible to others on the roadway while minimizing interference with other clothing and equipment. It is also likely that fluids may be leaking from the wrecked vehicle. Antifreeze, oil, and gasoline are common chemicals found at the scene of an MVC. These chemicals on the roadway can result in a slippery surface, creating a hazard for those walking or driving past. Consider traffic safety issues. A variety

of traffic incident management techniques may be appropriate. These techniques may include the use of personnel and traffic markers such as cones, flares, and signs to divert traffic around the area, and the strategic positioning of emergency vehicles to protect the area. Your ambulance can be a safe haven when caring for patients. Park your vehicle in an area that is a safe distance away, but in a place that allows you rapid access to equipment and your patient. Be aware of the dangers that may not be so apparent.

Look for possible dangers as you approach the scene and before you step out of the vehicle. Hazards found at the scene vary and may include traffic, chemical and biologic agents, electricity from downed power lines or lightning, secondary collapse of structures or terrain, fires, explosions, and carbon monoxide. Observe for unstable surfaces, slopes, ice, water, and wet grass. When gaining access to a patient, it is important to remember that you will typically leave via the same route you entered. When you leave, you will be moving a stretcher that weighs up to 100 pounds (45 kg), if it is motorized, and possibly a person weighing 200 pounds (90 kg) or more. If your footing was compromised going in, then you are going to have an even more difficult time coming out.

Working in unfavorable conditions and on unstable surfaces is a large part of prehospital care. Without knowing the infinite number of situations you may become involved in, a good rule to use is that any actions you may take to protect yourself (eg, wearing heavy coats, rain gear, or life jackets; using air conditioned or heated vehicles) should also be considered for the patient. If you are putting on equipment to address environmental hazards, then provide the patient with the same or similar equipment. If you move away from the scene to take cover from an environmental hazard, then move the patient with you if possible. Taking your time to stay focused on what you are doing will go a long way in preventing injuries to yourself and your patients.

Protect bystanders from becoming patients. Many bystanders attempt to help during an emergency; always remember that most are not trained to handle complicated EMS equipment, illnesses, or injuries.

Be aware of scenes that have the potential for violence. Request the assistance of law enforcement personnel if the scene is unsafe with the potential

FIGURE 10-2 If the scene is unsafe, then do not enter until measures have been taken to remedy the problem. An overturned vehicle may be unstable and should be shored up before trying to access the patient.

Courtesy of Rhonda Hunt.

for violence, and do not enter until the scene is declared safe. You will encounter violent patients, distraught family members, angry bystanders, gangs, and unruly crowds. When you enter the home of a patient, look around the immediate area. Are any weapons visible in the area to which a patient or others may have access? Weapons need not be typical like a knife or gun; they can also be items such as a screwdriver, hammer, or simple things sitting on the kitchen table or nightstand by the bed. Always observe for such objects, and if they are not secured, then place yourself between the patient and the potential danger to prevent possible access to the object. If the scene is a potential crime scene, then follow local protocols before entering. Ask for law enforcement personnel to accompany you when needed.

If the scene is unsafe and it is not possible to make it safe, then do not enter. Move to a safe location, and call for additional resources (eg, firefighters, utility workers, or hazmat technicians) (**FIGURE 10-2**). Chapter 40, *Vehicle Extrication, Special Rescue, and Hazardous Materials*, discusses patient rescue and extrication, and the hazards associated with responding to a hazmat incident, in more detail.

Determine Mechanism of Injury/Nature of Illness

When you perform the prehospital assessment, do not immediately categorize your patient as either a

Street Smarts

When you enter a potential crime scene, take care not to disturb possible evidence. If you must move an item (such as a gun lying on a patient's chest), then handle it carefully (never touching the trigger) with a gloved hand and thoroughly document the position in which it was found and to where it was moved. However, patient care takes precedence over evidence preservation. Never delay patient care to preserve a scene.

trauma (injured) patient or a medical (ill) patient. Some patients will have a problem that is not related to trauma, and they are typically referred to as medical patients (for example, patients with chest pain or difficulty breathing). Other patients will have sustained injuries in an incident such as a fall, an MVC, or a shooting, and they are usually considered trauma patients. Some patients fall into both categories. Consider the patient who is involved in an MVC after suffering a heart attack and losing control of the vehicle. This patient is a trauma patient who also has a medical condition.

Consider an unresponsive man found at the bottom of a ladder. Did he fall off the ladder, strike his head, and become unresponsive? Or did he experience a medical condition (such as hypoglycemia) that caused him to fall off the ladder and then become unresponsive? Early in the assessment, it can be difficult to identify with absolute certainty whether the emergency is of traumatic or medical origin. Remember, the fundamentals of good patient assessment do not change, despite the unique aspects of trauma and medical care.

Considering the mechanism of injury or nature of illness early will help you prepare for the rest of your assessment. For example, when you begin to gather equipment from the unit to treat your patient, you might collect different equipment for a patient who is reporting chest pain than you would for a pedestrian struck by a vehicle. As an AEMT, you need to be able to identify all aspects of the emergency to which you were called to respond.

Mechanism of Injury

Traumatic injuries are the result of physical forces applied to the outside of the body, usually from an object striking the body or a body striking an

FIGURE 10-3 With traumatic injuries, the patient has been exposed to some force or energy that has resulted in injury or possibly death. You can learn a great deal about that force by evaluating the mechanism of injury.

Courtesy of Rhonda Hunt.

object (**FIGURE 10-3**). These injuries are generally classified according to the type or amount of force applied to the body, the length of time the force was applied, and where it was applied on the body. The **mechanism of injury (MOI)** describes how the patient became injured. Examples of MOIs may include falls, MVCs, assaults, and industrial accidents. Determining the MOI will provide many clues to help you focus your assessment.

As you might expect, certain parts of the body are more easily injured than others. The brain and the spinal cord are fragile and easy to injure. Fortunately, they are protected by the skull, the vertebrae, and several layers of soft tissues. The eyes are also easily injured. Even small forces to the eyes may result in serious injury. The bones and certain organs are stronger and can absorb small forces without sustaining serious injury. A good understanding of anatomy and physiology will help you to identify times when an MOI may lead to injury to parts of the body not directly impacted. For example, consider a patient who has fallen off a roof, landing feetfirst. This patient's MOI would direct attention to possible injury to the feet. But significant energy likely transferred to other body areas and may have caused further injury in the patient's legs, pelvis, and spine.

You will commonly encounter the terms *blunt trauma* and *penetrating trauma*. With blunt trauma, the force of the injury occurs over a broad area, and

FIGURE 10-4 With blunt trauma, the force of the injury occurs over a broad area and the skin is not broken. However, the tissues and organs underneath the area of impact may be damaged.

Courtesy of Rhonda Hunt.

the skin is not broken (**FIGURE 10-4**). However, the tissues and organs underneath the area of impact may be damaged. With penetrating trauma, the force of the injury occurs at the specific point of contact between the skin and the object. The object pierces the skin and creates an open wound that carries a high potential for infection (**FIGURE 10-5**). The severity of injury depends on the characteristics of the penetrating object, the amount and length of time the force or energy was applied, and the part of the body affected. For more information about blunt and penetrating trauma, see Chapter 26, *Trauma Overview*.

Nature of Illness

As an AEMT, you are likely to care for more medical patients than trauma patients. For trauma patients, you examine the MOI as part of your scene size-up. For medical patients, attempt to determine

FIGURE 10-5 With penetrating trauma, an object pierces the skin and creates an open wound that carries a high potential for infection.

Courtesy of Rhonda Hunt.

the general type of illness, or **nature of illness (NOI)**. NOIs include seizures, heart attacks, diabetic conditions, and poisonings. The NOI is often best described by the patient's chief complaint and medical history.

To quickly determine the NOI, talk with the patient, family, and/or bystanders about the emergency. At the same time, use your senses to check the scene for clues to the possible cause of the illness. You may see open or spilled medicine containers, poisonous substances, unsanitary living conditions, open food on the counter, oxygen tanks, or home nebulizers. You may smell an unusual or strong odor, such as the odor of fresh paint in a closed room or the nauseating odor associated with gastrointestinal bleeding. You may hear abnormal sounds such as wheezes when the patient attempts

to breathe. Keep these observations of the scene in mind as you begin to assess the patient.

Take Standard Precautions

Standard precautions and **personal protective equipment (PPE)** need to be considered and adapted to the prehospital task at hand. PPE includes clothing and specialized equipment that provides protection to the wearer. The type of PPE used depends on the specific job duties required during a patient care interaction. For example, firefighters may wear PPE such as helmets, turnout gear, gloves, heat-resistant outerwear, and self-contained breathing apparatus designed to protect them from injury when performing a forced entry. Hazmat technicians may don a protective suit designed to prevent contamination by potentially lethal materials.

Standard precautions are protective measures that have traditionally been recommended by the Centers for Disease Control and Prevention (CDC) for use in dealing with objects, blood, body fluids, and other potential exposure risks of communicable disease. If you have a primary responsibility for patient care, then you need to take standard precautions when assessing and treating each and every patient. These measures may not provide absolute protection from exposure to infectious diseases or bloodborne pathogens, but they are the most effective way to reduce your risk of exposure. The concept of standard precautions assumes that all blood, body fluids (except sweat), nonintact skin, and mucous membranes may pose a substantial risk of infection. This concept includes potentially infectious materials that are dried, because some viruses (such as hepatitis) can live for days outside the body.

Take standard precautions before you step out of the EMS vehicle and before you make contact with the patient (**FIGURE 10-6**). After you have made contact with a patient, it is too late. The use of standard precautions in EMS may be dictated by local standards or protocols, and include (but are not limited to) consistent handwashing (with soap and water or alcohol-based hand cleansers) before and after care, gloves, eye protection, a mask, and a gown. At a minimum, gloves must be in place before any patient contact. Remember that after contact with a patient, gloves may be contaminated by infectious materials. Avoid handling EMS equipment

Safety

When everyone in the home is sick, consider an environmental cause—and be aware that the scene may be unsafe for you and your partner to enter. For example, when a stomach virus spreads through a family, one person generally gets better as another is affected; they do not all show signs and symptoms at the same time. However, exposure to carbon monoxide from a space heater would cause everyone in the enclosed area to develop signs and symptoms almost simultaneously.

FIGURE 10-6 Proper protective equipment is vital when you are called to a scene in which you may be exposed to blood or other body fluids.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

with the same gloves used during patient contact, and remember to change gloves before touching another patient. When eye protection is necessary, standard eyeglasses may not offer enough protection because most are not designed with side splash guards. Eyewear should protect you from potential exposures from all directions. Blood and body fluids that contain potentially infectious materials may become airborne; face masks reduce the risk of exposure associated with splash or spray. A mask will

provide protection from some airborne diseases, but its level of protection will depend on the type of mask, a proper fit, and your ability to apply and wear it properly.

You must be appropriately educated in the use of standard precautions, which should include training in the many types of PPE used in different situations. If you are not trained in the application of PPE that is appropriate for the situation, then do not approach the scene or make patient contact. Instead, call for additional help. If you make contact with the patient and discover a condition that warrants a higher level of PPE than you are using, then do not hesitate to regroup and upgrade your protection. For example, if you discover in your primary survey that a patient has a productive cough and a history of tuberculosis, and you are not wearing an N95 respirator, then you and your crew should immediately don appropriate respiratory protection. If you suspect you have been exposed to a communicable disease without the protection of proper PPE, then follow your local agency's protocols for postexposure reporting, testing, and prophylaxis.

Words of Wisdom

Standard precautions are the infection prevention practices intended to reduce the risk of transmission of bloodborne and other pathogens. These precautions include hand hygiene; use of personal protective equipment such as gloves, gowns, and masks; safe injection practices; safe handling of potentially contaminated equipment and surfaces; and respiratory hygiene/cough etiquette. The term *standard precautions* has replaced terms for similar concepts, such as *body substance isolation*, and is promoted by both the CDC and the World Health Organization.

Safety

In the context of community transmission of an aerosolized pathogen, such as during the COVID-19 pandemic, masks and eye protection must be considered part of the minimum protection used during all patient contacts.

Determine the Number of Patients

As part of the scene size-up, accurately identify the total number of patients. This evaluation is critical in determining your need for additional resources, such as additional ambulances. When multiple patients are present or more patients are present than

FIGURE 10-7 When multiple patients are present or more patients are present than the responding unit can effectively handle, use the incident command system, call for additional units, and begin triage.

Gavin Zeigler/Alamy Stock Photo.

the responding unit can effectively handle, put your mass-casualty plan into action based on your local protocols. This plan will most likely include establishing the **incident command system (ICS)**, calling for additional units, and then beginning triage (**FIGURE 10-7**). The ICS is a flexible system implemented to manage disasters and mass-casualty incidents in which section chiefs, including finance, logistics, operations, and planning, report to the person in charge of the incident, the incident commander. **Triage** is the process of sorting patients based on the severity of their conditions; usually, the most experienced EMS provider on scene is assigned to this role. After all patients have been triaged, you can begin to establish treatment and transport priorities. This process helps allocate personnel, equipment, and resources to provide the most effective care to everyone. Be familiar with the ICS and understand your local protocols. Incident command is discussed in more detail in Chapter 41, *Incident Management*.

Consider Additional or Specialized Resources

Some trauma or medical situations may require more ambulances, whereas others may have a need for specialized resources. Basic life support (BLS) units may be all that are needed for some patients; however, you should request paramedic backup for patients with severe injuries or complex medical conditions depending on available resources and local protocols. Air medical support may be another

good resource for advanced life support (ALS) in your area.

Fire departments usually provide services beyond fire suppression, including technical rescue, vehicle extrication, high-angle rope rescue, hazmat management, and swift water rescue. Specialized equipment and gear will also be needed for each of these specialized situations.

Street Smarts

You may substantially delay additional assistance if you wait until after you initiate patient care to make your initial request. Call as soon as you anticipate the need!

Search and rescue teams can help find, pack-age, and transport patients over long distances and across uneven terrain. Law enforcement personnel may also be needed to control traffic or intervene in potentially violent situations. Many police departments throughout the country have officers trained as first responders; they know cardiopulmonary resuscitation (CPR) and may carry an automated external defibrillator (AED). As mentioned previously, law enforcement personnel should be the first to enter crime scenes and hostile environments. Stage yourself and your vehicle at a safe distance until the scene has been secured.

Words of Wisdom

Some law enforcement personnel now carry tourniquets as part of the *Stop the Bleed* campaign, a federal initiative designed to teach bystanders how keep an injured person alive until the arrival of professional emergency responders.¹ This initiative was created to address life-threatening bleeding in situations such as active shooters, bombings, and any violent circumstances where immediate bleeding control may be instrumental in saving lives.

It is important to understand when additional or specialized resources are required and how your EMS system is organized. To determine if you require additional resources, ask yourself the following questions:

- How many patients are present?
- Are enough resources available to respond to their conditions?

- Does the scene pose a threat to you, your patient, or others?

Always call for additional resources as soon as possible, before making contact with patients or beginning triage. It is never wrong to call for backup, even if the extra units are instructed to turn back. Remember, you are less likely to ask for help after you begin patient care because at that point, you are part of the scene, particularly at an MVC in which patients require spinal immobilization or bleeding control.

Words of Wisdom

Based on the MOI or the situation in which the patient is found (such as a patient found on the ground with no witness to verify whether a fall occurred), you should consider cervical spinal immobilization. Assign a partner or another responder to place the head in a neutral inline position and to maintain stabilization until completely immobilized or it is determined that cervical spinal immobilization is not needed.

Patient Assessment

***Note:** The primary survey usually follows an ABCDE sequence (Airway, Breathing, Circulation, Disability, Exposure) or XABCDE in trauma patients (where X stands for exsanguinating hemorrhage), but if the patient appears lifeless or has severe external bleeding, use a CABDE sequence (Circulation, Airway, Breathing, Disability, Exposure).

Primary Survey

During the scene size-up, you use dispatch information and your own evaluation of the scene to identify potential hazards and determine if additional resources are needed. These steps are critical prior to the initiation of patient care. The essence of patient assessment, however, begins when you greet your patient and begin the primary survey.

The **primary survey** has a single, all-important goal: to identify and initiate treatment of immediate or imminent life threats. To do this, physically

examine the patient to assess the level of consciousness (LOC) and airway, breathing, circulation, disability, and exposure (ABCDEs). **Vital signs** are used to evaluate the patient's condition, but the primary survey is neither an in-depth physical exam nor an assessment of vital signs. Vital signs will be addressed later in the secondary assessment. During the primary survey, always give priority to life threats by assessing the patient's LOC and ABCDEs to ensure life-saving treatment, regardless of what other injuries may exist (**FIGURE 10-8**).

FIGURE 10-8 An assessment of the patient's level of consciousness and airway, breathing, circulation, disability, and exposure is used to establish whether the patient has a life-threatening condition and what you should do about it.

© Jones & Bartlett Learning.

Form a General Impression

Any time you meet someone new, you form a first impression about that person. Forming the **general impression** of your patient is a similar process that focuses on the rapid identification of potentially life-threatening problems and determines the priority of emergency medical care. This step includes noting things such as the person's age, sex, weight, level of distress, overall appearance, and the presence of any obvious bleeding. This information may lead you to anticipate different problems. A woman reporting abdominal pain, for example, may have a different spectrum of problems than a man with the same complaint because of the anatomy of the female reproductive system.

Think of your general impression as an overall visual assessment that helps you gather information as you approach the patient (**FIGURE 10-9**). You

FIGURE 10-9 As you approach the patient, form a general impression of the person's overall condition.

© David Degner/Contributor/Getty Images News/Getty Images.

can feel for pulses, pain, and deformities when you reach the patient. Ensure that you approach the patient from the front to avoid causing the patient to turn to see you, possibly making any injuries worse. Note the patient's position and whether the patient is moving or still.

Avoid standing over patients, if possible, especially if they are either seated or lying down. Instead, ensure you are at eye level with the patient. This practice shows respect for the patient and helps the patient feel more comfortable as you begin your assessment. Ensure the patient is breathing and assess the patient's skin color and condition as you begin. For example, is the patient's chest moving? Is the patient's skin pink, pale, gray, or cyanotic (blue)? Is it dry, clammy, or diaphoretic? Make note of odors that suggest chemical hazards, smoke, or alcohol on the patient's breath. If the patient is responsive, then introduce yourself and try to learn as much as possible about the chief complaint before you begin your exam. The patient's response can give you insight into the LOC, airway patency, respiratory status, and overall circulatory status before you begin your exam. Sometimes life-threatening conditions are obvious even during the general impression. Treat these conditions as soon as they are found.

Words of Wisdom

Any significant MOI, alteration in mental status, or abnormal finding with the ABCDEs is an indication your patient may be in critical condition!

You must answer the following questions to begin to form your general impression:

- Does the patient appear to have a life-threatening condition? Clues might include unresponsiveness, airway obstructions, obvious difficulty breathing, severe external bleeding, and cyanotic or very pale skin. If you suspect a life-threatening condition, then provide immediate care and transport.
- Was the patient injured? If so, then what was the MOI? On the basis of the MOI, would you expect the patient to be severely injured? If so, then assume the worst and begin treatment, including spinal immobilization.
- Does the patient seem coherent and able to answer questions? If not, then you need to rely more heavily on your physical assessment skills and/or the information that you can obtain from others at the scene.

Determine whether your patient's condition is stable, stable but potentially unstable, or unstable. This determination will direct further treatment and allows prehospital care providers to work together with an appropriate and consistent sense of urgency. However, you must constantly be aware of changes in the patient's condition.

If the primary problem appears to be traumatic, then maintain a high index of suspicion and begin treatment, including spinal immobilization. It is important not to have tunnel vision, but to be alert to the possibility that the traumatic event may have a medical origin. In many cases, medical emergencies and trauma go hand in hand.

Forming your general impression is your opportunity to evaluate “the big picture” before you focus on the patient's specific needs, so use all of your senses in observing the scene and the patient.

Words of Wisdom

Whether the patient is a medical or trauma patient has nothing to do with the severity of the patient's condition. Not every trauma patient is in critical condition, and not every medical patient is in stable condition. A patient who falls over a tree root and breaks two toes is a trauma patient, and a patient experiencing an MI is a medical patient. Categorize patients by the severity of their conditions, not whether their injuries or illnesses are traumatic or medical.

Assess Level of Consciousness

The patient's LOC can tell you a great deal about the patient's neurologic and physiologic status. The brain requires a constant supply of oxygen and glucose to function properly. In the primary survey, you need to ascertain only the gross LOC by determining which of the following three categories best fits your patient:

- Unresponsive
- Responsive with an altered LOC
- Responsive with an unaltered LOC

Sustained unresponsiveness in a patient indicates that a critical respiratory, circulatory, or central nervous system (CNS) problem may exist. Presume the patient has a critical injury or life-threatening condition until proven otherwise. Therefore, after rapidly assessing the patient and providing emergency treatment, package the patient and provide rapid transport to the hospital.

An altered LOC in a responsive patient may indicate that inadequate perfusion and oxygenation are adversely affecting the brain and its ability to function. An altered LOC in a responsive patient can also be caused by medications, drugs, alcohol, poisoning, hypoglycemia, chemical imbalances, and/or neurologic conditions. Further assessment will be required for any patient with an altered LOC.

When you assess a patient, determine the appropriateness of the patient's response by how well it demonstrates the patient's understanding and mental activity, not by how well it reflects your definition of socially acceptable behavior. You can evaluate mental status and LOC in just a few seconds by testing for **responsiveness** (the way in which a patient responds to external stimuli, including verbal stimuli [sound], tactile stimuli [touch], and painful stimuli) and orientation.

If you determine the patient has any indications to establish spinal motion restriction, then ensure the patient's cervical spine is manually stabilized by either you or another provider. If it is impossible to both manually stabilize the patient's cervical spine and continue your assessment to identify and correct life threats, then do your best to ensure the patient's spine remains in a stable position while you continue your primary survey.

The indicators for spinal motion restriction include the following:²

- Blunt trauma with any of the following findings:
 - An MOI that indicates the potential for spinal injury
 - Pain or tenderness on palpation of the neck or spine
 - Patient reports pain in the neck or back
 - Paralysis or neurologic complaint (numbness, tingling, partial paralysis of the legs or arms)
 - **Priapism** (male patients)
 - Altered mental status
 - Intoxication (alcohol or drugs)
 - Glasgow coma score of less than 14
 - Distracting injury (injury to another part of the body that potentially makes the patient's report of neck or spine pain unreliable)
 - Difficulty or inability to communicate

Use the mnemonic AVPU to assess a patient's LOC, depending on how well they respond to external stimuli. The **AVPU scale** tests the patient's responsiveness based on the following criteria:

- **Awake and alert.** The patient's eyes open spontaneously as you approach. The patient appears to be awake and aware of you. The patient is responsive to the environment, seems to follow commands, and visually tracks (follows) people and objects.
- **Responsive to Verbal stimuli.** The patient is not awake and alert. The patient's eyes do not open spontaneously as you approach. However, the patient's eyes open to verbal stimuli, and the patient is able to respond in some meaningful way when spoken to.
- **Responsive to Pressure.** The patient does not respond to your questions but moves or cries out in response to a pressure stimulus. Appropriate methods of applying a pressure stimulus include pinching the patient's earlobe (**FIGURE 10-10**). Be aware that some methods may not give an accurate result if a spinal cord injury is present.
- **Unresponsive.** The patient does not respond to a verbal or pressure stimulus. Unresponsive patients usually have no cough or gag reflexes and lack the ability to protect their airways. If you are in doubt about whether a patient

A

B

C

FIGURE 10-10 Appropriate methods of gauging a patient's responsiveness to pressure stimuli. **A.** Gently but firmly pinch the patient's earlobe. **B.** Press on the bone above the eye. **C.** Gently but firmly pinch the muscles of the neck.

© Jones & Bartlett Learning.

is truly unresponsive, then assume the worst and treat appropriately.

A patient who does not respond to your normal speaking voice, but who responds when you speak loudly, is responding to loud verbal stimuli. For a

FIGURE 10-11 Another method for gauging a patient's responsiveness to uncomfortable stimuli is to perform a sternal rub.

Courtesy of Rhonda Hunt.

patient who is deaf or hard of hearing, repeatedly tap the patient with your fingers. If the patient responds, then note the patient has a hearing impairment but responds to being tapped.

To determine whether a patient who does not respond to verbal stimuli will respond to pressure or uncomfortable stimulus, gently but firmly pinch the patient's skin. Areas where this technique works best are on the patient's earlobe, back of the upper arm (triceps), or the trapezius area (the muscle above the collarbone). A sternal rub is also effective for determining response to pressure. Firmly rub your knuckles against the patient's sternum in an up-and-down motion (**FIGURE 10-11**). Another effective technique is to provide upward pressure along the ridge of the orbital rim along the underside of the eyebrow. A patient who moans or withdraws is responding to the pressure stimulus. Be sure to note the type and location of the stimulus and how the patient responded.

If the patient does not respond to an uncomfortable stimulus on one side, then try to elicit a response on the other side. A patient who remains flaccid and does not move or make a sound is considered unresponsive.

Assess the Airway

As you move through the steps of the primary survey, always be alert for signs of airway obstruction. Regardless of the cause, a mild or severe airway obstruction will result in inadequate or absent airflow

into and out of the lungs, and therefore inadequate **perfusion** (the circulation of blood within an organ or tissue to provide necessary oxygen and nutrients and to remove waste) of the entire body. To prevent permanent damage to the brain, heart, and lungs, and even death, you must determine if the airway is open (patent) and adequate. Also, you must continually reassess the airway during the rest of patient assessment, care, and transport.

Responsive Patients

Patients of any age who are talking or crying are moving air, regardless of the quality. However, watching and listening to how patients speak, particularly patients with respiratory conditions, may provide important clues about the adequacy of their airways and the status of their breathing. A responsive patient who cannot speak or cry most likely has a severe airway obstruction.

Words of Wisdom

If the patient has a history of trauma or a potential history of trauma, then use the jaw-thrust maneuver to open the airway. If no risk of trauma exists, then use the head tilt–chin lift maneuver.

If you identify an airway problem, then stop the assessment process and work to clear the patient's airway. This action may be as simple as positioning the patient so the air moves in and out, suctioning liquids from the airway, or removing an obvious foreign body from the patient's mouth. It may be as complex as providing abdominal thrusts or chest compressions to remove a foreign body from the airway. Do not continue the assessment until the airway is clear. Although airway and breathing problems are not the same, the signs and symptoms often overlap. If your patient has signs of difficulty breathing or is not breathing, then immediately take corrective actions using appropriate airway management techniques.

Unresponsive Patients

With an unresponsive patient or a patient with a decreased LOC, immediately assess the patency of the airway. Unresponsive patients should be considered to have experienced a traumatic event. If the

FIGURE 10-12 The jaw-thrust maneuver.

© Jones & Bartlett Learning. Courtesy of MIESS.

potential for trauma exists, then use the jaw-thrust maneuver to open the airway (**FIGURE 10-12**). If you cannot obtain a patent airway using the jaw-thrust maneuver, or if you can confirm that the patient did not experience a traumatic event, then use the head tilt–chin lift maneuver to open and maintain a patent airway. Another cause of airway obstruction in an unresponsive patient could be relaxation of the tongue muscles, allowing the tongue to fall to the back of the throat. Address this obstruction by first positioning the airway, followed by placing an oral or nasal airway. Dentures, blood clots, vomitus,

mucus, food, and other foreign objects may also create an airway obstruction. These can be cleared with manual techniques and suctioning. After you confirm the airway is clear, you can continue your assessment. All of these techniques are described in Chapter 11, *Airway Management*.

Signs of airway obstruction in an unresponsive patient include the following:

- Obvious trauma, blood, or other obstruction
- Noisy breathing, such as snoring, bubbling, gurgling, crowing, stridor, or other abnormal **breath sounds**. Normal, or eupneic breathing is quiet.
- Extremely shallow or absent breathing. Airway obstructions may impair breathing.

If any of the aforementioned conditions exist, then the airway is considered inadequate. Open the airway using the appropriate method (either the head tilt–chin lift or jaw-thrust maneuver), suction as necessary, and use an airway adjunct as necessary. The body will not be supplied with the oxygen needed to survive if the airway is not managed quickly and efficiently. Remember that airway positioning depends on the age and size of your patient. For trauma patients or patients with an unknown illness, manually stabilize the cervical spine while using the jaw-thrust maneuver to open the airway.

YOU are the Provider

Part 2

As you arrive on scene, you note a single vehicle that has driven off the road and collided with a large tree. The grill of the vehicle is crushed in, almost to the firewall, but there is no intrusion into the passenger compartment. As soon as the driver positions your ambulance in a safe location that shields the scene, you grab your jump bag and proceed to the wrecked vehicle. You find the driver of the vehicle restrained in the seat by a lap and shoulder belt, and note that the windshield is cracked in multiple places. Liquid is pooling under the vehicle. You speak to the patient as you open the door. She is now alert and reporting neck pain.

Recording Time: 0 Minutes

Appearance	Alert
Level of consciousness	Alert, but confused
Airway	Patent
Breathing	Nonlabored
Circulation	Warm and dry

3. Does this patient present more like a medical patient or a trauma patient?
4. What type of PPE should you wear for this type of call?

Assess Breathing

A patient's breathing status is directly related to the adequacy of the airway. After you have made sure the patient's airway is open, ensure the patient's breathing is present and adequate. A patient who is breathing without assistance is said to have **spontaneous respirations** or spontaneous breathing.

As you assess the patient's breathing, ask yourself the following questions:

- Does the patient appear to be choking?
- Is the respiratory rate too fast or too slow?
- Are the patient's respirations shallow or deep?
- Is the patient cyanotic?
- Do you hear abnormal breath sounds when listening to the lungs?
- Is the patient moving air into and out of the lungs on both sides?

Each complete breath includes two distinct phases: inspiration and expiration. During inspiration (inhalation), the diaphragm and intercostal muscles contract and the chest rises up and out, drawing oxygenated air into the lungs. During expiration (exhalation), the muscles relax and the chest returns to its original position, releasing air with an increased carbon dioxide level out of the lungs. Inhalation and exhalation times occur in a 1:3 ratio; the active inhalation phase lasts one-third the amount of time of the passive exhalation phase.

Breathing is a continuous process in which each breath regularly follows the last with no notable interruption. Breathing is normally a spontaneous, automatic process that occurs without conscious thought, visible effort, marked sounds, or pain. Rapidly assess respirations to determine the following:

- Is the rate normal, fast, or slow?
- Is the depth normal or shallow?
- Is chest rise equal or unequal?

Assess the patient's breathing and listen to breath sounds with a stethoscope over each lung. Chest rise and breath sounds should be equal on both sides of the chest. When you assess breathing, you must obtain the following information:

- Respiratory rate (the normal rate is 12 to 20 breaths/min in adults)
- Quality and character of breathing
- Degree of distress
- Use of **accessory muscles** in the chest or neck

Never withhold oxygen from any patient who is having difficulty breathing. Oxygen may also be appropriate for patients who are breathing adequately in some situations. Provide positive-pressure ventilations for patients who are apneic or whose breathing is too slow, too fast, or too shallow. If the patient is breathing adequately but remains hypoxic, then administer oxygen. The goal for oxygenation for most patients is an oxygen saturation level of approximately 94% to 99%.

If a patient develops difficulty breathing after your primary survey, then immediately reevaluate the airway. If the airway is open and breathing is present and adequate, then consider administering supplemental oxygen. If breathing is present and inadequate because respirations are too fast (generally more than 20 breaths/min), too shallow, or too slow (generally fewer than 12 breaths/min), then administer supplemental oxygen. When respirations exceed 28 breaths/min or are fewer than 8 breaths/min with signs of inadequate tidal volume, then consider providing positive-pressure ventilation and using an airway adjunct if the patient will tolerate one. Tidal volume is discussed in more detail later in this chapter. Remember that air exchange is the critical issue, not simply the number of breaths.

Words of Wisdom

When you assess respirations, always pay attention to the events leading up to the assessment. A patient who just completed a marathon will have rapid and deep respirations, whereas a patient who is sleeping will have slow and shallow respirations. These patients do not require positive-pressure ventilation. The rate and depth of respirations change with metabolic need.

Observe how much effort is required for the patient to breathe. Normal respirations are not usually shallow or excessively deep. **Shallow respirations** can be identified by little movement of the chest wall (reduced tidal volume) or poor chest excursion. Deep respirations cause a significant rise and fall of the chest. Document when the patient's respirations are shallow or deep.

Normal breathing is an effortless process that does not affect a patient's speech, posture, or positioning. Breathing that becomes progressively more difficult requires progressively more effort. When you can see that effort, the patient's breathing is

described as **labored breathing**. Initially, labored breathing is characterized by the patient's position, concentration on breathing, and the increased effort and depth of each breath. As breathing becomes more labored, accessory muscles are used, which include the neck muscles (sternocleidomastoid), the chest's pectoralis major muscles, and the abdominal muscles. The presence of **retractions** (indentations above or below the clavicles [supraclavicular and subclavicular] and in the spaces between the ribs [intercostal]) is also a sign of inadequate breathing. The patient may make grunting sounds with each breath. Sometimes the patient may be gasping. In pediatric patients, **nasal flaring**, seesaw breathing, and supraclavicular and intercostal retractions indicate inadequate breathing. Speech is a good indicator of whether a responsive patient is having difficulty breathing. A patient who can speak smoothly without unusual extra pauses is breathing normally. A patient who can speak only two or three words without pausing to take a breath, a condition known as **two- to three-word dyspnea**, has a serious breathing problem.

Patients who are having marked difficulty breathing will instinctively assume a posture in which it is easier for them to breathe, or will be on their feet pacing around. Two common postures indicate that the patient is trying to increase airflow. The first position is called the **tripod position** (**FIGURE 10-13**). In this position, a patient is sitting and leaning forward on outstretched arms with the head and chin thrust slightly forward; significant conscious effort is required for breathing. The second position is most commonly seen in children—the **sniffing position**. The patient may be sitting upright or lying on their back, but in either case, the head and chin are thrust slightly forward to keep the airway open, such that the patient appears to be sniffing (**FIGURE 10-14**). Those patients who are unable to change position to assist with breathing are often in the most distress.

Infants (age 1 month to 1 year) and small children may have labored breathing for a sustained period, but will then become exhausted and will no longer have the strength to maintain the necessary energy to breathe. In infants and small children, cardiac arrest is generally caused by respiratory arrest.

Respiratory distress occurs when a patient has difficulty breathing; therefore, the work of breathing is increased. Typically, a person in respiratory distress

FIGURE 10-13 A patient in the tripod position will sit leaning forward on outstretched arms with the head and chin thrust slightly forward.

TABLE 10-1 Signs of Respiratory Distress and Failure

Respiratory Distress	Respiratory Failure
Agitation, anxiety, restlessness	Lethargy, difficult to rouse
Stridor, wheezing	Tachypnea (increased respirations) with periods of bradypnea (decreased respirations) or agonal respirations
Accessory muscle use (sternocleidomastoid), intercostal retractions	Inadequate chest rise/poor excursion
Tachypnea	Inadequate respiratory rate or effort
Mild tachycardia	Bradycardia (decreased heart rate)
Nasal flaring, seesaw breathing, head bobbing	Diminished muscle tone

© Jones & Bartlett Learning.

presents with an increase in respiratory effort and rate. **Respiratory failure** occurs when the blood is inadequately oxygenated or ventilation is inadequate to meet the oxygen demands of the body and is often caused by a combination of inadequate tidal volume, respiratory rate, and/or airway obstruction. Respiratory arrest is the ultimate result of respiratory failure if the failure is not corrected (**TABLE 10-1**).

Words of Wisdom

Normal breathing should be quiet and not grossly evident to you. If you see or hear the patient breathe, then the person may have a problem.

Assess Circulation

Assessing circulation helps you to evaluate how well blood is circulating to the major organs, including the brain, lungs, heart, and kidneys, and the rest of the body. A variety of emergencies can impair circulation, including blood loss, shock, and conditions that affect the heart and major blood vessels. Circulation is evaluated by assessing the patient’s mental status, pulse, and skin condition. You will also need to identify and control severe external bleeding.

Special Populations

You can feel the pulse of a child at the carotid artery, as in an adult. However, palpating the carotid pulse in an infant may present a problem. An infant’s neck is often short and fat and the pulse is often fast, so it may be difficult to find the carotid pulse. Because of the infant’s soft, immature trachea, palpating the carotid artery may cause injury. Therefore, in children younger than 1 year, palpate the brachial artery to assess the pulse (discussed later in this chapter).

Assess the Pulse

With each beat of the heart, the ventricles contract, forcefully ejecting blood from the heart and propelling it into the arteries. Often referred to as the heartbeat, the **pulse** is the pressure wave that occurs as each ventricular contraction causes a surge in the blood circulating through the arteries. The pulse is most easily felt at a pulse point where a major artery lies near the surface and can be pressed gently against a bone or solid organ.

Your first consideration when assessing for circulation is to determine whether the patient has a pulse. To do so, hold together your index and long fingers and place the tips over a pulse point, pressing gently against the artery until you feel intermittent pulsations. In responsive patients who are older than 1 year, **palpate** (feel) the radial pulse at the wrist (**FIGURE 10-15A**). In unresponsive patients older than 1 year, palpate the carotid pulse in the neck (**FIGURE 10-15B**). When you palpate the carotid pulse, place the tips of your index and long fingers in the center of the throat on the trachea. Next, slide your fingers toward you into the groove between the trachea and the neck muscle to position your fingers directly over the carotid artery. Palpate the carotid pulse on the same side of the patient that you are on; palpating on the opposite side of the patient may lead to undue pressure on the neck that may compromise respirations. Use caution when palpating the carotid pulse in a responsive patient, especially an older patient. Only use gentle pressure on one side of the neck. Never press on the carotid arteries on both sides of the neck at the same time. Doing so can reduce circulation to the brain.

Sometimes, you may have to slide your fingertips a little to either side and press again until you feel

A

B

FIGURE 10-15 A. To palpate the radial pulse, place the tips of your index and long fingers over the radial artery, pressing gently until you feel intermittent pulsations. **B.** To palpate the carotid pulse, place the tips of your index and long fingers over the carotid artery, pressing gently until you feel intermittent pulsations.

© Jones & Bartlett Learning.

a pulse. When you palpate a pulse, do not use your thumb because you may mistake the strong pulsing circulation in your thumb for the patient's pulse. The normal pulse rate for an adult is 60 to 100 beats/min.

Palpate the brachial pulse, located at the medial area (inside) of the upper arm, in children younger than 1 year (**FIGURE 10-16**). With the infant lying supine, you can access the brachial pulse by elevating the arm over the infant's head. Because most infants have chubby arms, you need to press your adjacent fingertips firmly along the brachial artery, which lies parallel to the long axis of the upper arm, to be able to palpate the pulse.

During the primary survey, assess the pulse to determine the following:

- If it is present or absent
- If it is normal, fast, or slow
- If it is weak and thready or strong and bounding

FIGURE 10-16 To palpate the brachial pulse in an infant, press firmly along the brachial artery on the inside of the upper arm.

© Jones & Bartlett Learning.

You also need to determine the adequacy of the pulse during the secondary assessment. This step is done by assessing the pulse rate, pulse rhythm, and pulse character, discussed later.

If you cannot palpate a pulse in an unresponsive patient, then begin CPR. If an AED is available, then attach it and follow the voice prompts, following your local protocol. An AED is indicated for use on patients who are unresponsive, apneic, and pulseless. An AED with special pediatric pads and a dose-attenuating system is indicated for use on pediatric patients younger than 8 years; if this equipment is unavailable, then use an adult AED.³ In infants, it is preferable to perform manual defibrillation or use a dose-attenuating system; if these methods are unavailable, then use an adult AED. More information about CPR and AEDs is available in Chapter 15, *BLS Resuscitation*.

Words of Wisdom

Manual defibrillation is an ALS skill that is not within your scope of practice as an AEMT. If both paramedic backup and pediatric-sized pads are unavailable, then use adult-sized pads with the AED for children and infants. Ensure the pads do not touch on children; for infants, place one pad on the chest and one pad on the back.

If the patient has a pulse but is not breathing, then provide ventilations at a rate of 10 to 12 breaths/min for adults and 12 to 20 breaths/min

for an infant or a child. Continue to monitor the pulse to evaluate the effectiveness of your ventilations. If at any time the pulse is lost, then start CPR and apply the AED. The apparent absence of a palpable pulse in a responsive patient is not caused by cardiac arrest. Therefore, never begin CPR or use an AED on a responsive patient.

Assess the Skin

The skin has many functions. It helps maintain the water content of the body, acts as insulation and protection from infection, and has a role in regulating body temperature by changing the amount of blood circulating through the surface of skin.

Assessing the skin is one of the most important and most readily accessible ways of evaluating circulation and perfusion, blood oxygen level, and body temperature. A normally functioning circulatory system perfuses the skin with oxygenated blood. A lack of perfusion or hypoperfusion will result in hypoxia of the brain, lungs, heart, and kidneys. The degree of hypoperfusion and how long it lasts will determine if a patient will sustain permanent damage related to the hypoxia. Perfusion is assessed by evaluating a patient's skin color, temperature, moisture, and capillary refill.

Skin Color

Many blood vessels lie near the surface of the skin. The color of the skin is determined by the blood circulating through these vessels and the amount and type of pigment present in the skin. Blood is red when it is adequately saturated with oxygen. As a result, the skin in lightly pigmented people is pink. The pigmentation in most people will not hide changes in the underlying color of the skin, regardless of the person's race. In patients with deeply pigmented skin, changes in color may be apparent only in certain areas, such as the fingernail beds, the mucous membranes in the mouth, the lips, the underside of the arm, and palm (which are usually less pigmented), and the conjunctiva of the eyes. The **conjunctiva** is the delicate membrane lining the eyelids, and it covers the exposed surface of the eye. In addition, you should assess the palms of the hands and soles of the feet in infants and children.

Inadequate peripheral circulation will cause the skin to appear pale, white, ashen, or gray, possibly with a waxy, translucent appearance like a

FIGURE 10-17 Cyanosis occurs when a patient has a low level of oxygen in the blood.

© St. Bartholomew's Hospital, London/Photo Researchers, Inc.

white candle. Abnormally cold or frozen skin may also appear this way. When the blood is not properly saturated with oxygen, it appears blue. Therefore, in a patient with insufficient air exchange and a low level of oxygen in the blood, the blood and vessels become blue, and the lips, mucous membranes, nail beds, and skin over the blood vessels appear blue or gray. This condition is called **cyanosis** (**FIGURE 10-17**).

High blood pressure may cause the skin to be abnormally flushed and red. In some patients with extremely high blood pressure, all of the visible blood vessels will be so full that the skin will appear to be a dark red-purple. A patient with a significant fever, heatstroke, sunburn, mild thermal burns, or other conditions in which the body is unable to properly dissipate heat will also appear to have red skin.

Changes in skin color may also result from chronic illness. Liver disease or dysfunction may

cause **jaundice**, resulting in the patient's skin and sclera turning yellow. The **sclera** is the normally white portion of the eye and may show color changes even before skin color change is visible.

Skin Temperature

Normal skin temperature will be warm to the touch; normal body temperature is 98.6°F (37°C). Abnormal skin temperatures are hot, cool, cold, and clammy. Clammy is considered cool and moist. When a patient has a significant fever, sunburn, or hyperthermia, the skin feels hot to the touch. The skin will feel cool when the patient is in early shock, has mild hypothermia, or has inadequate perfusion. With poor perfusion, the body redirects blood flow away from the surface of the skin and diverts it to the core of the body. The result is cool, pale, clammy skin; in your primary survey, this finding is a good indication of hypoperfusion and inadequacy of circulatory system function (shock). The skin will feel cold when the patient is in profound shock, has hypothermia, or has frostbite (frozen tissue).

Body temperature is normally measured with a thermometer in the hospital. However, in the field, feeling the patient's torso, underneath clothing with the back of your hand, is usually adequate to determine whether the patient's temperature is either elevated or decreased.

Skin Moisture

Dry skin is normal. Skin that is wet or moist from sweat, or excessively dry and hot, suggests a problem. In the early stages of shock, the skin will become slightly moist. Skin that is only slightly moist but not covered excessively with sweat is described as clammy, damp, or moist. When the skin is bathed in sweat, such as after strenuous exercise or when the patient is in shock, the skin is described as wet or **diaphoretic**.

Because the color, temperature, and moisture of the skin are often related signs, consider them together. When you record or report your assessment of the skin, first describe the color, then the temperature, and last, whether the skin is dry, moist, or wet. For example, you could say or write, "Skin: pale, cool, and clammy."

Again, these characteristics are important findings in your primary survey because hypoperfusion

can lead to serious consequences if treatment is delayed.

Capillary Refill

Capillary refill is often evaluated in pediatric patients to assess the ability of the circulatory system to restore blood to or perfuse the capillary system in the fingers and toes. When evaluated in an uninjured limb, capillary refill time (CRT) may provide an indication of the pediatric patient's level of perfusion. However, especially in adult patients, capillary refill can be affected by the patient's body temperature, position, preexisting medical conditions, history of smoking, and medications. Therefore, capillary refill is useful in children and infants, but it is not considered reliable and is a less valuable indication of perfusion in adults. Other conditions that are unrelated to the body's circulation may also slow capillary refill. These conditions include exposure to a cold environment, hypothermia, frostbite, and **vasoconstriction** (narrowing of a blood vessel, such as with hypoperfusion or cold extremities). Injuries to bones and muscles of the extremities may cause local circulatory compromise, resulting in hypoperfusion of an extremity rather than hypoperfusion of the body in general.

To test capillary refill, place your thumb on the patient's fingernail with your fingers on the underside of the patient's finger and gently compress (**FIGURE 10-18A**). The blood will be forced from the capillaries in the nail bed. Remove the pressure applied against the tip of the patient's finger. The nail bed will remain blanched (white) for a brief period. As the underlying capillaries refill with blood, the nail bed will be restored to its normal pink color.

Capillary refill should be prompt, and the nail bed color should be pink. With adequate perfusion, the color in the nail bed should be restored to its normal pink color within 2 seconds, or about the time it takes to say "capillary refill" at a normal rate of speech (**FIGURE 10-18B**). For a CRT of 2 seconds or less, report and document it as normal. Suspect poor peripheral circulation when capillary refill takes more than 2 seconds or the nail bed remains blanched. In this case, report and document the CRT as delayed, or CRT more than 2 seconds.

A blue color may indicate that the capillaries are refilling with blood drawn from the veins rather than with oxygenated blood from the arteries, making the test invalid. Consider the capillary refill test

**A****B**

FIGURE 10-18 **A.** To test capillary refill, gently compress the fingertip until it blanches. **B.** Release the fingertip, and count until it returns to its normal pink color.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

a poor indicator of overall perfusion if the patient is in or has been exposed to a cold environment or if the patient is older. In both situations, delayed capillary refill may be normal.

To assess capillary refill in older infants and children younger than 6 years, press on the skin or nail bed and determine how long it takes for the pink color to return. In newborns and young infants, press on the forehead, chin, or sternum to determine CRT. As with adults, capillary refill should be restored within 2 seconds. Suspect poor peripheral circulation when capillary refill takes more than 2 seconds or the nail bed remains blanched. In this case, report and document the CRT as delayed,

or CRT more than 2 seconds. Again, delayed capillary refill is not considered an accurate indication of poor perfusion in adult patients.

Assess and Control External Bleeding

Identify and immediately control any major external bleeding. In some patients, rapid blood loss can quickly result in shock or even death. Therefore, this step demands your immediate attention and should be performed before addressing airway or breathing concerns. Signs of blood loss include active bleeding from wounds and/or evidence of bleeding such as blood on the clothes or near the patient. Serious bleeding from a large vein may be characterized by steady blood flow. Bleeding from an artery is characterized by a spurting flow of blood. When you evaluate an unresponsive patient, do a sweep for blood quickly and lightly by running your gloved hands from head to toe, pausing periodically to see if your gloves are bloody.

Direct pressure with a gloved hand and followed by a sterile bandage over the wound will control bleeding in most cases. Direct pressure stops the bleeding and helps the blood to coagulate (clot) naturally. Most minor bleeding can be adequately controlled by using direct pressure. When direct pressure is not quickly successful or whenever you encounter obvious arterial hemorrhage of an extremity, apply a tourniquet. More information about controlling bleeding and applying a tourniquet is found in Chapter 27, *Bleeding*.

Restoring Circulation

If a patient has inadequate circulation, then take immediate action to restore or improve circulation, control severe bleeding, and improve oxygen delivery to the tissues. The apparent absence of a palpable pulse in a responsive patient is indicative of a low cardiac output state—not cardiac arrest. However, if you cannot feel a pulse in an unresponsive adult, then begin CPR if an AED or manual defibrillator is not readily available. Once an AED or manual defibrillator is available, immediately assess the need for defibrillation. Remember to take standard precautions, which may include use of a barrier device for ventilation, gloves, and protective eyewear.

Continued impaired circulation is devastating to the body's cells because it deprives the cells of

vital oxygen, which is necessary for cell function. CPR and bleeding control are intended to maintain circulation. Oxygen delivery is improved through the administration of 100% supplemental oxygen. Any patient with impaired circulation should receive high-flow oxygen via a nonrebreathing mask or assisted ventilation to improve oxygen delivery at the cellular level.

Assess the Patient for Disability

After you have examined the patient's ABCs and addressed any life-threatening conditions, perform a brief neurologic evaluation of the patient.

It is important to determine, if possible, the patient's normal mental status. A number of circumstances—including ongoing illness and/or history of stroke, traumatic brain injury, developmental delay, Alzheimer disease, and more—may cause a patient to have a baseline mental status that is not fully alert and oriented. Any deviation from alert and oriented to person, place, time, and event, or from a patient's normal baseline, is considered an **altered mental status**.

Words of Wisdom

The Glasgow Coma Scale (GCS) is the most common method of assessing mental status and neurologic function. Although it may take slightly longer to calculate the patient's GCS score compared with the AVPU scale, it provides much greater insight into the patient's overall neurologic function. The GCS is covered in more detail in the secondary assessment section of this chapter.

For patients who are alert and responsive to verbal stimuli, next evaluate their orientation. **Orientation** tests patients' mental status by checking their memory and thinking ability. The most common test evaluates a patient's ability to remember four things:

- **Person.** The patient is able to give their name.
- **Place.** The patient is able to identify their current location.
- **Time.** The patient is able to tell you the current year, month, and approximate date.
- **Event.** The patient is able to describe what happened (the MOI or NOI).

These questions were not selected at random. They evaluate long-term memory (person and place), intermediate memory (place and time), and short-term memory (time and event). If the patient knows these facts, then the patient is said to be "alert and fully oriented," "alert and oriented to person, place, time, and event," or "alert and oriented $\times$ 4."

As mentioned previously, the **Glasgow Coma Scale (GCS)** is the most commonly employed, reliable, and consistent method of assessing mental status and neurologic function. It assigns a point value (score) for eye opening, verbal response, and motor response; these values are added for a total score (**TABLE 10-2**). When you report and record your findings, be sure to include the score for each GCS category, not just a cumulative score.

To illustrate how the GCS works, consider the following scenario. You encounter an older man who tracks you with his eyes as you enter his room. As you speak with the man, you note that his verbal response is disoriented, even though he follows your commands. His GCS values would be 4, 4, and 6, for a total score of 14. By comparison, if the patient opened his eyes only to an uncomfortable stimulus, moaned as the only verbal response, and withdrew to pressure, then he would be assigned GCS values of 2, 2, and 4, for a total score of 8.

Special Populations

Mental status may be difficult to evaluate in children. First, determine whether the child is alert. Even infants should be alert to your presence and track you with their eyes. Ask the parent or caregiver whether the child is behaving normally, particularly in regard to alertness. Most children older than 2 years know their own names and the names of their parents and siblings. Evaluate mental status in school-age children by asking about recent holidays, school activities, or the names of teachers.

Expose Then Cover

As you physically examine the patient, visually inspect each area to ensure an accurate and thorough assessment. Although not every patient needs to be completely exposed for appropriate assessment to occur, keep in mind that you cannot assess what you cannot see. Therefore, adequate exposure of each area being examined is essential to the physical

TABLE 10-2 Glasgow Coma Scale^a

Eye Opening		Best Verbal Response		Best Motor Response	
Spontaneous	4	Oriented conversation	5	Obeys commands	6
In response to sound	3	Confused conversation	4	Localizes to pressure	5
In response to pressure	2	Words	3	Withdraws from pressure	4
None	1	Sounds	2	Abnormal flexion	3
		None	1	Extension	2
				None	1

^aSome systems use a “Not testable (NT)” score for any element that cannot be tested. Eye opening cannot be tested in a patient whose eyes are closed due to a local factor, such as swelling; verbal response cannot be tested in a patient who has a preexisting factor interfering with communication, such as mutism; and motor response cannot be tested in a patient who has preexisting paralysis or other limiting factor.

Score: 13–15 may indicate mild dysfunction, although 15 is the score a person without neurologic impairment would receive.

Score: 9–12 may indicate moderate dysfunction.

Score: 8 or less is indicative of severe dysfunction.

© Jones & Bartlett Learning.

exam process. When you are finished, cover up patients to respect their privacy and to maintain body heat. The steps for performing a rapid physical exam are discussed next.

Performing a Rapid Full-Body Scan

It takes about 60 to 90 seconds to perform a **rapid full-body scan** of the patient’s body to identify other injuries that must be managed and/or protected before the patient is transported. This scan should be thorough yet quick. This is an abbreviated exam as opposed to the systematic exam that you perform during the secondary assessment.

The exam you perform is based on the needs of your patient. The following are guidelines on how and what to assess during the rapid full-body scan:

- **Inspection.** Inspection is simply looking at your patient for abnormalities. Look for anything that may indicate a problem. For example, swelling in a lower extremity may indicate an acute injury or a chronic illness.
- **Palpation.** Palpation describes the process of touching or feeling the patient for abnormalities. At times palpation is gentle, and at other times it is firmer and will help you to identify where the patient has pain. Your fingertips are

best suited for detecting texture and consistency, whereas the back of your hand is best suited for noting temperature.

- **Auscultation.** **Auscultation** is the process of listening to sounds the body makes by using a stethoscope. For example, when measuring a patient’s blood pressure, you listen to the flow of blood against the brachial artery with the head of the stethoscope. This process is auscultation of a blood pressure.

DCAP-BTLS is a mnemonic to remind you what to look for when you are inspecting and palpating various body regions. Each area of the body is evaluated for the following:

- **D** Deformities
- **C** Contusions
- **A** Abrasions
- **P** Punctures/penetrations (and paradoxical movement in the chest)
- **B** Burns
- **T** Tenderness
- **L** Lacerations
- **S** Swelling

To perform a rapid full-body scan of the patient to identify and treat life threats, follow the steps in **SKILL DRILL 10-1**. Remember, this exam should take no longer than 60 to 90 seconds!

Skill Drill 10-1 Performing a Rapid Full-Body Scan

Step 1

Assess the head, looking and feeling for DCAP-BTLS and crepitus (a grating or grinding sensation or sound made when two pieces of broken bone are rubbed together). Have your partner maintain in-line stabilization if trauma is suspected.

Step 2

Assess the neck, looking and feeling for DCAP-BTLS, step-offs where the cervical vertebrae are not aligned properly, jugular venous distention, tracheal deviation from midline in the neck, and crepitus.

Step 3

In trauma patients, apply a cervical collar when applicable.

Step 4

Assess the chest, looking and feeling for DCAP-BTLS, paradoxical motion, subcutaneous emphysema, and crepitus. Listen to breath sounds on both sides of the patient's chest.

(continues)

Skill Drill 10-1 Performing a Rapid Full-Body Scan *(continued)*

Step 5

Assess the abdomen, looking and feeling for DCAP-BTLS, rigidity (firm or soft), guarding, rebound tenderness, and distention.

Step 6

Assess the pelvis, looking for DCAP-BTLS. If no pain is present, then gently compress the pelvis downward and inward to look for tenderness and instability.

Step 7

Assess all four extremities, looking and feeling for DCAP-BTLS. Also assess bilaterally for distal pulses and motor and sensory function.

Step 8

Assess the back and buttocks, looking and feeling for DCAP-BTLS. In all trauma patients, maintain in-line stabilization of the spine while log rolling the patient onto the side in one motion. Do not log roll the patient if any instability in the pelvis is present. Instead, gently run your hands under each side of the patient as far as possible to note any obvious injuries or bleeding.

Words of Wisdom

If you are placing the patient on a long backboard, then it is particularly important that you check the back before log rolling the patient onto a backboard.

Identify and Treat Life Threats

Many conditions present an immediate threat to life. The key to your role as an AEMT is to determine if a life threat is present and, if so, to quickly address it. The human body responds quickly and adapts to maintain perfusion when a catastrophic situation occurs. Your role is to recognize the signs and symptoms associated with that response and determine the cause of the patient's presentation.

The first observation that you will most likely make is that the patient is extremely anxious, followed by a loss of meaningful communication between you and the patient. Severely sick or injured people become less aware of their surroundings and stop making attempts to communicate. After a variable period, loss of consciousness occurs. The patient becomes totally unresponsive to external stimuli. The muscles become slack, among them the muscles of the jaw, thus permitting the tongue to sag against the posterior part of the throat. This in turn leads quickly to airway obstruction. Air can no longer enter the lungs, and within a few minutes the patient stops breathing, cutting off the intake of oxygen and the release of carbon dioxide. The heart cannot continue to function without oxygen, and it stops beating. Within a few minutes, a number of brain cells begin to die, leading to irreversible brain damage. Only a few general conditions can cause sudden death: airway obstruction, respiratory arrest, respiratory failure, primary cardiac arrest, shock, and severe bleeding. Often, these conditions are manageable or even reversible, but you have to be able to recognize them quickly and take immediate steps to correct them. This is the purpose of the primary survey.

Life-saving interventions begin with you opening the airway and assessing its patency. Airway patency is your number one priority. Assess the patient's breathing, and initiate ventilations in patients who have either inadequate respirations

or no respirations at all. Although a range of "normal" respiratory rates exist, always assess your patient's overall condition to decide on appropriate treatment. It is important to assess the quality of respirations, mental status, skin color, appearance, and chest rise. Respirations that are shallow may not be ventilating and oxygenating the patient adequately. Next assess the patient's pulse. If the patient is pulseless, then initiate chest compressions. Assess the skin for color, moisture, and temperature. If any of these signs are inadequate, then initiate treatment for shock. If the cause of shock is identifiable, then attempt to correct the problem. A common example of a life-threatening cause of shock is severe bleeding. The detection of severe bleeding is the last life-saving intervention. Severe external bleeding must be controlled using direct pressure and/or a tourniquet. (See Chapter 14, *Shock*, for more information on shock, and Chapter 15, *BLS Resuscitation*, regarding chest compressions.)

In most cases, identifying and correcting life-threatening issues begins with the assessment of the ABCDEs. However, when a patient is in cardiac arrest, you should assess the ABCDEs simultaneously in the interest of minimizing the time to first compression. Also, when a patient has life-threatening bleeding, it is more appropriate to first address life threats to circulation, following a sequence of circulation, airway, breathing, disability, and exposure (CABDE). In these cases, controlling life-threatening bleeding takes priority over airway and breathing concerns.

Determine Priority of Patient Care and Transport

As you complete your primary survey, you will need to make some decisions about patient care and transport. If you do not identify any injuries that require treatment or rapid transport when completing your assessment of the ABCDEs, then you may find indications for rapid transport during your rapid full-body scan of the patient's body (**FIGURE 10-19**). The rapid full-body scan will assist you in determining transport priority. For example, you may identify an internal hemorrhage by the presence of a distended or firm abdomen or bilateral femoral fractures. These types of conditions would be indications for rapid transport.

FIGURE 10-19 Identifying priority patients.

Courtesy of the U.S. Department of Transportation.

Would you consider your patient a high, medium, or low priority for transport? Priority designation is used to determine if your patient needs rapid transport or will tolerate a few more minutes on scene. Patients with any of the following conditions are examples of high-priority patients and should be transported immediately:

- Difficulty breathing
- Serious MOI
- Poor general impression
- Any alteration in mental status
- Severe chest pain
- Pale skin or other signs of poor perfusion
- Complicated childbirth
- Uncontrolled bleeding
- Responsive but unable to follow commands
- Severe pain in any area of the body
- Inability to move any part of the body

Protecting the patient's spine and identifying fractured extremities are integral parts of packaging for transport (**FIGURE 10-20**). If you suspect a spinal injury or the MOI is significant enough to cause a possible injury, then consider establishing spinal motion restriction early. Be certain to understand your local protocols with regard to how to achieve such motion restriction. These injuries can be made worse if you neglect to assess and treat them before moving the patient.

Recognizing the need to transport serious trauma patients is of such importance that you may hear colleagues refer to the **Golden Hour** (sometimes called the Golden Period), which refers to the

FIGURE 10-20 If you suspect a spinal injury has occurred, then establish spinal motion restriction.

© Jones & Bartlett Learning.

FIGURE 10-21 The Golden Hour, also called the Golden Period, is the time during which treatment of shock or traumatic injuries is most critical and the potential for survival is best.

© Jones & Bartlett Learning.

time from injury to definitive care, during which treatment of shock and traumatic injuries should occur because the potential for survival is best (**FIGURE 10-21**). Over time, it is increasingly difficult for the body to compensate for shock and traumatic injuries. For this reason, spend as little time as possible on scene with patients who have sustained significant or severe trauma. Aim to assess, stabilize, package, and begin transport to the appropriate facility within 10 minutes (often referred to as the “Platinum 10”) after arrival on scene whenever possible. However, a difficult or complex extrication may obviously limit possibilities.

Some patients may benefit from remaining on scene and receiving continuing emergency medical care. For example, an older patient with chest pain may be better served on scene by receiving nitroglycerin and aspirin and waiting for paramedic backup than by rapid transport. Call for support from paramedics if a unit is not already en route to the scene. Depending on the travel distance, a paramedic unit can be met while transporting a patient in critical condition. If paramedic assistance is delayed or farther away, then coordinating a rendezvous may be a better decision for a high-priority patient. Your decision to stay on scene or transport immediately will be based on your patient's condition, the availability of more advanced help, the distance you must transport, and your local protocols.

Correct identification of high-priority patients is an essential aspect of the primary survey and helps to improve patient outcome. Although initial treatment is important, it is essential to remember that rapid transport is one of the keys to the survival of any high-priority patient. Initiate transport as soon as practical and possible.

Remember, the goal of your primary survey is to identify and treat life threats, including management of the ABCs, as quickly as possible. Measuring vital signs more exactly is accomplished during the secondary assessment (discussed later), after time and life threats are less of an issue.

If the patient's condition is stable, then reassess vital signs every 15 minutes until you reach the emergency department (ED). If the patient's condition is unstable, then reassess vital signs every 5 minutes (or as often as the situation permits), while looking for trends in the patient's condition, and treat for shock.

Do not be falsely reassured by apparently normal vital signs. The body has amazing abilities to compensate for severe injury or illness, especially in children and young adults. Even patients who have experienced severe medical or traumatic conditions may initially present with fairly normal vital signs. However, the patient's body eventually loses its ability to compensate (decompensated shock), and the vital signs may deteriorate rapidly, especially in children. In fact, this tendency for the vital signs to fall rapidly as the patient decompensates

YOU are the Provider

Part 3

You are able to gain access to the patient without difficulty, and you inform your partner to maintain manual stabilization of the spine while you begin your initial assessment. You perform a quick primary survey and find no immediate life threats. She is alert, but confused about the crash. You notice she has a large hematoma on her forehead. Her airway is patent, she is breathing adequately, and she has no bleeding that you can see. Her radial pulses are strong and regular, and her skin is warm and dry. You calculate her GCS score as 14. Her breath sounds are clear and equal bilaterally. Although she has no signs of respiratory distress, you place her on oxygen via nonrebreathing mask due to the MOI. She has good pulses, motor function, and sensation in all extremities, but reports a tingling sensation. No other injuries are found during your rapid exam, but you do find a medic alert bracelet that says "Diabetic."

Recording Time: 10 Minutes

Respirations	18 breaths/min; clear
Pulse	90 beats/min; regular
Skin	Warm and dry
Blood pressure	118/76 mm Hg
Oxygen saturation (SpO ₂)	99% on oxygen at 15 L/min
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

5. What are the components of the GCS score?
6. How can you rule in or rule out diabetes as the cause of her altered mental status?

is the reason that it is important to frequently re-check and record vital signs. Treating a patient for shock before obvious signs of shock occur helps to reduce the overall effects of decompensated shock and, therefore, potentially increases your patient's chance of survival.

Words of Wisdom

Reassess vital signs often, watching for trends such as decreasing mental status that may indicate a patient is unable to compensate for illness or injury. Suspect shock in any patient with tachycardia and pale, cool, clammy skin, and transport immediately.

Reconsider the MOI

As part of the scene size-up, you evaluated the MOI before you began treatment. At this point in the assessment process, look at the MOI again to ensure you have not missed important information. Understanding the MOI helps you to understand the potential severity of the patient's problem and provides valuable information to hospital staff as well. Some patients have experienced a significant MOI; others clearly have not. The MOI will also

serve as a guide during the secondary assessment phase, discussed later. Significant MOIs are listed in **TABLE 10-3**.

Seat belts and airbags have significantly reduced the death and disability associated with MVCs. However, be aware that seat belts and airbags can also cause injuries. When you evaluate a patient who was involved in an MVC, look for signs and ask questions to determine whether seat belts and/or an airbag were involved, and document the use or nonuse in your patient care report. Also include whether or not airbags deployed. During your handoff report at the hospital, ensure that you tell hospital personnel whether seat belts were worn, whether the airbag deployed, and the extent of damage to the vehicle.

Words of Wisdom

When you assess a patient, always consider occult injuries. Occult injuries are those that are not visible to the eye. Occult injuries include damage to internal organs, such as a lacerated liver from impact with a steering wheel.

TABLE 10-3 Significant MOIs

Age Group	MOI
Adults	• Ejection from a vehicle • Death of another person in the same vehicle • Fall from a height greater than 20 feet (6 m) • Vehicle rollover • High-speed (>40 mph) vehicle crash • Vehicle-pedestrian collision • Motorcycle crash • Unresponsiveness or altered mental status following trauma • Penetrating trauma to the head, chest, or abdomen
Children	All MOIs in the preceding list for adults, with the following additions or modifications: • Fall greater than 10 feet (3 m) or two to three times the child's height • Fall of less than 10 feet (3 m) with loss of consciousness • Medium- to high-speed vehicle crash (≥ 25 mph) • Bicycle crash

Abbreviation: MOI, mechanism of injury

Patient Assessment

History Taking

History taking provides details about the patient's chief complaint and an account of the patient's signs and symptoms. Although history taking is listed after the primary survey, it is an integral part of the assessment and should be initiated on scene simultaneously with other tasks. You or your partner may ask questions of people in the vicinity while the other initiates patient assessment. It is important to gather as much history as possible on scene from family, friends, and bystanders because this information may be lost forever if not retrieved at this time. Also check for medical identification tags and paperwork to gain essential information concerning events leading up to the incident. If the patient is able to answer questions or a family member is transported in the ambulance with the patient,

then history taking can be expanded en route. Sometimes history may be essential to determine the underlying illness or injury. Do not delay transport for patients who are in unstable condition.

It is important to document all of the information gathered during this phase of the assessment process, including demographic information (age, race, sex), past medical history, and current health status of the patient, along with any pertinent family history and recent travel history when relevant.

Investigate the Chief Complaint

The patient's chief complaint is the most serious thing that the patient is concerned about. It is usually the reason the patient or someone else called 9-1-1 (**FIGURE 10-22**). To investigate the chief

FIGURE 10-22 The patient's initial response to the question "What's wrong?" is the chief complaint.

© Jones & Bartlett Learning.

complaint, begin by making introductions, make the patient feel comfortable, and obtain permission to treat. Then you can then start your investigation by asking a few simple, open-ended questions. Refer to the patient as "Mr.," "Ms.," or "Mrs.," using the patient's last name. Avoid using terms such as "honey" and "sweetie." If you cannot obtain the patient's name, then "ma'am" or "sir" is appropriate. Questions such as, "What seems to be the matter?" or "What's wrong today?" should produce a response that will help determine a chief complaint. These questions and others can help to elicit a response that may determine the patient's highest concern. The response is usually expressed in the patient's own words with simple answers, such as "My chest hurts" or "I have been feeling weak." Use eye contact and body position to encourage the patient to continue speaking, and repeat statements back to the patient to show that you understand the situation. Do not interrupt, and be empathetic of the patient's situation. As discussed previously, the problems or feelings the patient reports to you are the symptoms. Symptoms cannot be felt or observed by others. Signs are objective conditions that can be seen, heard, felt, smelled, or measured by you or others.

You must consider the wide range of age groups that you will interact with as an AEMT. Information from infants and children may come from a parent or caregiver. Older patients might be slow to respond or have multiple complaints. Over time, you will develop your own particular technique or style for communicating with patients of various ages.

FIGURE 10-23 If the patient is unresponsive, then try to obtain a pertinent history or patient information from family or bystanders.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

You will also gather information about the chief complaint from observable clues and information received from the original dispatch. If the patient is unresponsive, then you may obtain information about the patient, pertinent past medical history, and clues about the immediate incident from family members, a person who may have witnessed the situation, medical alert jewelry, or other forms of patient medical history documentation (**FIGURE 10-23**). Observable clues may include conditions such as two- to three-word dyspnea (when the patient can only speak two to three words before pausing to take a breath). These clues may indicate the patient's chief complaint is "difficulty breathing," or the clues may be part of a bigger problem that has to do with a lengthy history of cardiac conditions.

Consider the following scenario: You respond to a call to the home of an older man who fell. This information was provided by the dispatcher, and you can use it to help process all of the clues that may be presented in what appears to be a simple fall. You find the patient lying at the bottom of the stairs. How many stairs are there, are they carpeted, and is the floor concrete, wood, or tile? Do you see a throw rug that may have caused the patient to trip and fall? You note that the patient has an obvious deformity of his right arm, and you suspect a possible fracture. Is this deformity the patient's chief complaint, or is the deformity the result of another problem? The patient states he fell, which is how the injury occurred, and he is reporting pain in the

right arm. However, was the fall the result of tripping on a step, or was it associated with a medical condition such as dizziness, vertigo, or a syncopal episode? It is your responsibility to look at all the possibilities and ask the appropriate questions to determine the patient's chief complaint.

Sorting through the clues from the emergency scene itself, from the patient's complaints, and from the patient's signs and symptoms and past medical history will assist you in understanding the cause of your patient's problem and enable you to make appropriate, timely decisions about your patient's care. Remember to use family members, friends, bystanders, other public safety personnel, and medical identification tags to gain essential information concerning events leading up to the incident (**FIGURE 10-24**). The patient's history will help to tie together your findings from the primary survey.

Words of Wisdom

The chief complaint is what you are actually called for. The primary problem is what is actually wrong with the patient. For example, you may be called out for a patient with difficulty breathing. On assessment, you find that the patient has pulmonary edema and chest pain because of heart failure. The chief complaint is "dyspnea," and the primary problem is "heart failure."

FIGURE 10-24 Medical identification tags.

Courtesy of Rhonda Hunt.

Investigate the History of Present Illness (OPQRST)

As you learn about the chief complaint, broaden your knowledge to include the circumstances surrounding the complaint, or the history of the present illness. You can remember the six most important circumstances by using the mnemonic **OPQRST**, which stands for the following:

- O** Onset
- P** Provocation/palliation
- Q** Quality
- R** Region/radiation
- S** Severity
- T** Timing

This mnemonic is generally used when assessing a patient who reports pain or dyspnea. The OPQRST mnemonic is discussed in more detail in the following sections.

Onset

The onset refers to when the patient's problem began and what the patient was doing at the time of the incident. Ask the patient when the problem started or when the incident occurred, and how long ago the patient first noticed the problem. Chest pain that started while the patient was sleeping may be more significant than chest pain that started while the patient was pushing a lawn mower in extreme heat. If the patient reports that the problem started a long time ago (days or weeks), then also ask, "What prompted you to call now?" In most cases, the patient will note a sudden worsening of the problem or an additional problem that compounded the first one. For example, a patient who has experienced shortness of breath for the past 3 days may have called because of an onset of chest pain an hour ago. You often will not learn about this second problem unless you ask.

For patients with traumatic problems, there may be a delay between when they were hurt and when they called. Again, ask them why they delayed and what prompted them to call today. The information they give may be valuable to you and the ED staff.

Provocation/Palliation

Learning about provoking and palliating factors (also known as aggravating or alleviating factors)

can be extremely helpful in determining the cause and severity of the patient's problem. Provoking factors include anything that seems to bring on the problem or that seems to make the problem worse, such as increased shortness of breath during exertion. Palliating factors include anything that brings the patient relief from the problem, such as sitting down to rest. Note the position in which the patient is found on arrival.

The answers to these questions often help you to identify the potential cause. For example, shortness of breath that started when the patient climbed a set of stairs may be respiratory or cardiac in origin. These questions are often the clues to hidden medical conditions from traumatic incidents. When you ask if anything makes the pain better or worse, the patient may report that the pain has been worse "since I fell last week," uncovering a traumatic event that was not previously reported.

Quality

The patient's description of the pain may be useful when trying to determine the cause of the problem. For example, patients who are having a heart attack classically describe their chest pain as "squeezing" or "pressure," although they may also say things such as, "My chest feels heavy." To learn about the quality of the pain, ask patients to describe how they feel. Avoid asking the patient leading questions when possible, such as those that can be simply answered yes or no; this approach may not give you an accurate description of what the patient actually feels. Remember that not all patients experience pain in the same way, and an older patient may deny the presence of chest pain but may state, "My chest just feels heavy."

Patients often initially say, "I don't know," or "It's hard to describe." Once again, the key is for you to have patience. If you wait, then most patients will ultimately describe the quality of their pain. Carefully document in the patient's own words; this information may be significant to other health care providers who become involved in the patient's care. Some patients have limited vocabulary when it comes to their bodies; it may be best to let them simply point to their pain, rather than describe it. Ask patients to point to the area of pain, describe the area of pain, or describe pain anywhere else

associated with the problem. If the patient still cannot describe the pain or if the patient cannot speak, then you might consider offering several descriptions of pain and letting the patient choose. For example, you might ask, "Which of these words best describes your pain: Sharp or dull? Burning? Stabbing? Crushing? Throbbing?"

You can learn a great deal about the patient's problem through these questions. For example, patients who point to a single place for their pain have what is known as **focal pain** (**FIGURE 10-25A**). Many problems, such as fractures and areas of inflammation, commonly cause focal pain. However, some patients cannot point to a single location. Instead, they often rub their hands across their chests or abdomens as they are asked to point to their pain. These patients are experiencing **diffuse pain** (**FIGURE 10-25B**). Several conditions, including heart attack and internal bleeding, typically cause diffuse pain.

Words of Wisdom

Your documentation of any pain complaint should include a description in the patient's words and your findings from the other OPQRST questions. Record all pain complaints in detail. Not all pain symptoms are "classic"; the exact description may help hospital personnel make the correct diagnosis in a case that is not typical.

Region/Radiation

Patients can often provide clues about the cause of their problems by describing the region or location of any pain or discomfort. **Radiating pain** refers to an area of the body from which the origin of pain or discomfort may travel (**FIGURE 10-25C**). The presence of radiating pain will not alter your treatment much; however, physicians and nurses caring for the patient in the hospital may be interested in hearing about areas of radiation. For example, a patient who is having a heart attack may report chest pain that radiates to the left arm and jaw. Carefully document what you learn.

Be careful how you ask about radiation of pain. Most patients will not understand if you ask, "Does your pain radiate anywhere else?" The best way to

FIGURE 10-25 A. Focal pain. B. Diffuse pain. C. Radiating pain.

© Jones & Bartlett Learning.

ask patients about radiation is to ask, “Do you have pain or discomfort anywhere else?” or, “Does it feel like the pain moves around?”

Referred pain is pain that exists in more than one place, without a “trail” of pain in between. For example, it is common for a patient with gallbladder disease to report pain in the right upper quadrant of the abdomen and in the right shoulder. However, there is no pain between the right upper quadrant and right shoulder. There may also be pain only in an area that is not the source of the pain.

Severity

Severity refers to the patient’s perception of “how bad” the current incident is in comparison with others. In some cases, particularly when the patient has experienced the problem before, this perception provides extremely useful information. For example, a patient with asthma may provide helpful information by comparing this episode with previous asthma attacks. However, if the problem has never occurred, the patient’s perception of severity may not be useful except as a guide to whether the problem is getting worse or better during transport.

To assess severity, you may ask the following questions:

- “How bad is this episode in comparison with previous ones?” (if the problem is chronic or recurring)
- “What happened the last time you had an episode this bad?” (if the problem is chronic or recurring)
- “How would you rate this problem in numbers, if 0 is normal (that is, pain-free) and 10 is the worst pain or discomfort you can imagine?”

For patients with chronic problems, obtaining the answer to the question, “What happened the last time you had an episode this bad?” is invaluable. In most cases, patients are accurate in their self-assessments of severity. For example, patients with asthma might tell you that the last time they experienced an episode this bad, they were intubated and spent 2 weeks in the intensive care unit. The patient’s comments tell you about the severity of the episode relative to prior episodes. Complete your assessment and provide rapid transport. At the other extreme, patients might tell you they

were kept in the ED for a short time and then discharged. Obviously, these two types of episodes are vastly different in urgency, and you can adjust your plans for treatment and transport accordingly. Bear in mind, however, that no relationship may exist between the severity of previous incidents and the current one; treat patients as they present, keeping past information in mind.

Another way to evaluate changes in the patient's condition during your treatment and transport is to use a numeric rating system. For example, a patient with an apparent broken leg might initially tell you that the pain is an 8 on a scale of 1 to 10. After you have applied oxygen, splinted the leg, and begun transport, recheck the patient's pain perception. If the pain is now a 9, then you might consider changing the position of the leg, using an ice pack, or, if allowed by local protocol, administering analgesic medications such as nitrous oxide. However, if the pain level is now reportedly a 5, then you know that the treatment is effective (at least for now). Remember, patients perceive pain in different ways, so it is inappropriate to compare one patient's numeric rating with another patient's rating.

Time

The questions related to time provide information about when the problem began. You might want to find out whether the problem has been constant or intermittent. If the patient states that the problem is intermittent, then ask what seemed to make it better or worse.

The answers to these questions will further help you and other health care providers involved with the patient's care to understand the nature of the problem. Some conditions, such as those involving abdominal organs, have classically intermittent pain. Other problems, such as fractures, typically have constant pain.

Interventions

You may hear the mnemonic *OPQRST-I* used. The letter *I* refers to interventions. Some patients may self-treat or self-medicate before calling 9-1-1. For example, a patient reporting chest pain may have taken nitroglycerin or aspirin before your arrival. It is pertinent to ask about any treatment prior to EMS arrival to avoid overdosing a patient by administering a medication that may already have been used

prior to your arrival and to note the possible interactions between medications. People may try a variety of home remedies for whatever is ailing them. Be sure to ask; this information may affect your treatment of the patient.

Identify Pertinent Negatives

During the process of achieving a thorough history, you must also document pertinent negatives. **Pertinent negatives** are findings you would expect based on the patient's complaint, but that are not present. For example, you would expect a patient reporting severe abdominal pain to have a tender abdomen and possible nausea and/or vomiting. An abdomen that is soft and nontender on palpation or the lack of nausea or vomiting are all pertinent negatives. These are signs and symptoms that the patient does not have. Pertinent negatives also indicate that a thorough and complete exam and history were performed. Pertinent negatives will vary with each patient interaction.

Investigate the Past Medical History (SAMPLE History)

As you obtain a patient history from medical and trauma patients, you need to know some of the standard techniques for interviewing patients. By obtaining a **SAMPLE history**, a brief history of the patient's condition, you will be able to gather important information from the patient. Use the mnemonic SAMPLE to obtain the following information:

- S Signs and symptoms.** What signs and symptoms occurred at the onset of the incident? Does the patient report pain?
- A Allergies.** Is the patient allergic to any medication, food, or other pertinent substance? What reactions did the patient have to any of them? If the patient has no known drug allergies, note this on the run report as "no known drug allergies" or "NKDA."
- M Medications.** What medication or medications is the patient prescribed? What dosage is prescribed? How often does the patient take the medication? What prescription, over-the-counter (OTC), and herbal medications has the patient taken in the last 12 hours? Many people do not consider herbal or OTC medications to be medications. They may

leave out this information unless specifically questioned. How much was taken and when? Does the patient take recreational drugs or drink alcohol?

- P** *Pertinent past medical history.* Does the patient have any history of medical, surgical, or trauma occurrences? Has the patient had a recent illness or injury, fall, or blow to the head? Is there important family history that should be known? Has the patient ever had this problem before? If so, then how was it treated previously?
- L** *Last oral intake and last menstrual cycle.* When did the patient last eat or drink? What did the patient eat or drink, and how much was consumed? Did the patient take any drugs or drink alcohol? Has there been any other oral intake in the last 4 hours? For females of childbearing age, what was the date of the last menstrual cycle?
- E** *Events leading up to the illness or injury.* What are the key events that led up to this incident? What occurred between the onset of the incident and your arrival? What was the patient doing when this illness started? What was the patient doing when this injury happened?

Street Smarts

When you interview a patient about medical history, it is helpful to ask, "What medications do you take?" Otherwise, you may find that the patient denies any history but has multiple prescriptions (polypharmacy). For example, when asked about having seizures, a patient may deny having them even though prescriptions exist in the patient's name for antiseizure medications. The typical answer when asked about the medication is, "No, I don't have seizures as long as I take my medicine."

Obtaining the History on Sensitive Topics

Alcohol and Drugs

The signs and symptoms a patient may present with while under the influence of alcohol or drugs may be confusing, hidden, or disguised. Many patients who abuse alcohol and/or drugs may deny

FIGURE 10-26 Many vehicle crashes involve alcohol. In these cases, the patient history may be unreliable.

©Jack Dagley Photography/Shutterstock.

the abuse. Families, friends, and coworkers may be unaware that a patient has any drug or alcohol dependencies. The reasons patients deny using alcohol or drugs can vary greatly. It may be out of fear of losing their employment or driver's license, worry about what friends and others such as health care providers may think about them, and embarrassment or insecurity about their dependency.

The history that you gather from a patient with a chemical dependency may be unreliable (**FIGURE 10-26**). If patients are not telling the people closest to them that they have a problem, then you, as an outsider, may have even less success in obtaining information about a patient's current dependency. The signs and symptoms of alcohol or drug use may be masked by the patient's presentation. Use all of your senses when providing patient care.

Establish a strong rapport with your patients. Do not judge a patient who may have a chemical dependency, and be professional in your approach. Be honest and open. Foremost, impress on the patient that information received will be kept in confidence. Then and only then, a patient may open up to you and provide information that can be valuable in assessment and treatment.

Physical Abuse or Violence

You must report all cases of suspected physical abuse or domestic violence to the appropriate authorities. Follow your state laws and local protocols when dealing with such cases. If you suspect a patient is a survivor of physical abuse or domestic violence, then do not accuse any person of being responsible for the situation. Instead, immediately involve law enforcement.

Because abuse and physical violence are sensitive situations, look for hidden clues that such a situation exists. Information gathered at the scene, during the assessment process, and while transporting a patient may indicate violence or abuse.

What should you look for? When obtaining a history, note whether the information provided by the patient and others present at the scene is inconsistent. Do you observe multiple injuries in various stages of healing? Are some bruises red, black, brown, or even green? In some cases, a survivor of abuse or violence will not tell you what happened because of fear of further violence when EMS is not present. The patients may not answer your questions because the physical aggressor is present and is answering questions for them. In these cases, separate the people present and interview both parties about the situation.

In cases of domestic violence, involvement can be extremely dangerous. If you determine that the emergency response is part of a domestic abuse situation, then call law enforcement personnel immediately (**FIGURE 10-27**).

When involved with cases of physical abuse, be observant and open-minded, have a high index of suspicion, and be nonjudgmental. Accurate and thorough documentation is very important in cases of abuse and domestic violence. Your documentation should be an objective report of the facts. Avoid subjective, judgmental statements, and include any pertinent statements made by the patient or others present using quotation marks. Remember, these prehospital situations could possibly involve some type of legal process in the future. You may be

FIGURE 10-27 Do not handle potentially violent calls alone. Summon law enforcement personnel immediately.

© PEDRO PARDO/AFP/Getty Images.

summoned at a later date to provide testimony regarding what may have happened.

Sexual History

Your ability to obtain information about a patient's sexual history may be limited. Religious beliefs, cultural stereotypes, and societal expectations may have a major role in patients' decisions of whether to reveal the personal side of their lives, including practices considered by some people to be bizarre or exotic. In addition, most patients find sharing information regarding their sexual histories with others to be uncomfortable.

When would information about a patient's sexual history become important? As an AEMT, you will be involved in the care of female patients reporting lower abdominal pain. Consider all female patients of childbearing age who report lower abdominal pain to be pregnant unless ruled out by history or other information. Questions to ask when faced with this prehospital scenario include the following:

- When was your last menstrual period?
- Are your periods normal? (Is any vaginal discharge or bleeding present that is not associated with a menstrual period?)
- Do you have urinary frequency or burning?
- What is the severity of cramping?
- Are any unpleasant odors present?
- Is it possible you may be pregnant?
- Are you taking birth control pills or using other types of birth control?
- How many sexual partners do you have?
- Have you had recent sexual encounters?

When dealing with a male patient, you must inquire about urinary symptoms:

- Do you have any pain associated with urination?
- Do you have any discharge, sores, or an increase in urination?
- Do you have burning or difficulty voiding?
- Has any trauma occurred?
- How many sexual partners do you have?
- Have you had recent sexual encounters?

When potentially relevant, ask about the potential for sexually transmitted diseases. Providing this information may be difficult and uncomfortable for the patient. Never be judgmental about the response to your questions. All patients should be and expect to be treated with compassion and

respect. All information obtained from a patient for the purpose of determining a treatment plan is confidential; do not share it with others unless necessary in the process of treating the patient's medical or traumatic condition.

Words of Wisdom

Mission-Critical Communications

Mission-critical communications are any communications in which disruption will result in the failure of the task at hand. Although mission-critical communications will change from industry to industry, many of the problems encountered as well as recommendations to help avoid errors and improve effectiveness can be employed by EMS providers.

A concept central to mission-critical communications is the shared **mental model**. A mental model is the picture individuals have in their head of "what's going on." Even though individuals on a team may be in different roles, seeing different things from different perspectives, for any team to work effectively together, all members must share a mental model. The goal of mission-critical communications is an efficient, effective, and error-free transfer of the mental model. When providers have different ideas of "what's going on," situational awareness fails and problems begin.

For an individual health care provider or a team to build a mental model, the following sequence of four questions must be answered:

1. What is the focused priority for the patient? (What is the crux of the problem?)
2. What is the history of prior care? (What got us to this point?)
3. What is the patient's current state? (Where are we right now?)
4. What are the patient's immediate needs? (What is the very next thing that needs to happen?)

Answering these four questions quickly and efficiently will not just help avoid errors and misunderstandings, it will provide a handoff that allows receiving clinicians to continue forward progress in patient care rather than spending time with unnecessary questions and clarifications or feeling the need to begin a patient interview and assessment from scratch.

Special Challenges in Obtaining the Patient History

Each patient presents a unique assessment challenge. Those with physical limitations or unusual behavioral tendencies may prove particularly difficult

to understand and therefore assess. As a result, you may miss critical information or become discouraged by the patient's inability to communicate clearly. Therefore, it is important that you develop strategies that assist in gathering pertinent information while at the same time avoiding potential frustration that can come from difficult communications.

Silence

Dealing with patients who say very little or nothing at all can be difficult and frustrating. Patience is extremely important when dealing with patients and their emergency crises. Patients may be thinking about how to answer you, getting the facts straight, or assessing your crew to determine if they feel comfortable answering you. Using a closed-ended question that requires a simple yes or no answer may work best. Consider whether the silence is a clue to the patient's chief complaint. Also consider whether something about your communication style could be making the patient uncomfortable, and try to alter your technique to be as sensitive, empathetic, and professional as possible.

Always look for visual signs in the patient's environment that may indicate why a patient is not communicating. In addition, look for nonverbal clues, including facial expressions that may show pain or fear. Is the patient distressed or intimidated by your presence? How is the patient sitting or standing? Is there a communication problem? Is there a language problem? The number of reasons a patient may be silent during the prehospital encounter is endless. A good AEMT will continue to assess the situation and find a way to effectively communicate with the patient.

Overly Talkative

On the other end of the spectrum is the patient or bystander who is extremely talkative. Some people just talk a lot, and gathering details about their medical conditions may be difficult if they talk around your question or you have a difficult time refocusing the patient's conversation. Some possible causes as to why a patient may be overly talkative could include excessive caffeine consumption, nervousness, and ingestion of cocaine or methamphetamines.

After you have allowed a talkative patient a chance to talk, you must keep the patient focused

on the questions asked. Direct the patient to stick to the facts by summarizing statements frequently, and clarify statements for the purpose of making sure the information you are gathering is correct. Remember, there is no such thing as too much information.

Multiple Symptoms

Some patients present with multiple symptoms, particularly older patients. Be prepared to spend extra time assessing the patient owing to possible challenges with communication. Prioritize the patient's complaints as you would during triage; start with the most serious and end with the least serious. Always ask for additional information to determine why EMS was called.

Keep an open mind, and do not focus on one complaint or detail to determine a treatment plan. Always remember there may be a number of possible medical or traumatic causes for a patient's chief complaint.

Anxiety

When a person is involved in an emergency situation, it is natural for that person to appear excited or anxious. Many people have not been faced with a true emergency during their lifetime, and their reactions may be unpredictable. As an AEMT, you are trained to handle stressful situations. Your patient or bystander may be nervous, pacing, vocal, panicked, or, in some extreme cases, experiencing complete hysteria. It is your responsibility to deal not only with the emergency crisis at hand, but also with the people present who are having difficulties coping with the situation. Frequently, anxious patients can be observed in emergency scenes that involve a large number of patients, such as during a disaster. Anxiety also can be observed or encountered during a routine EMS call when family members or patients cannot cope.

You can expect anxious patients to exhibit signs of psychological shock, such as pallor, diaphoresis, shortness of breath, numbness in the hands and feet, dizziness or light-headedness, and even loss of consciousness. Some anxious people may have no real medical complaint but may be hiding or concealing information, such as trying to keep a family member, friend, or employer from discovering their dependency on alcohol or drugs. Patients may have

been involved in a physical abuse or domestic situation that they want to keep quiet. In any situation involving anxious patients, you must be aware of verbal and nonverbal clues. Is the patient making sense during a verbal conversation? Anxiety can also be an early indicator of low blood glucose level, shock, or hypoxia. Perform the appropriate exam to rule out these potentially life-threatening causes early in your assessment.

During a crisis situation, reassure the patient that any nervous or anxious response is normal and can be overcome. It may be possible for you to control an anxious patient by simply smiling or using a delicate and therapeutic touch, if the patient seems receptive to touch. Be confident in your approach and have a positive demeanor. In many patient care interactions, your presence may be all that is required to calm the patient.

As in every response, safety is a paramount concern. Be aware that emergency responses involving anxious and possibly hysterical patients can turn violent. A confident but cautious AEMT can prevent a bad situation from getting worse, and they can calm and control anxious patients, friends, and family members in a professional manner.

Special Populations

When you deal with pediatric patients, be sure to involve them in their own care. Give choices, but avoid questions with "yes" or "no" answers. For example, do not ask "Can I touch your tummy?" Rather, give the child a choice, such as the following: "I need to listen to your breathing and also touch your tummy. Which would you like for me to do first?" This practice allows participation without limiting your emergency medical care.

Anger and Hostility

Every patient encounter has the potential for violence and hostility, from a situation involving a 9-year-old boy who was hit by a vehicle to a 90-year-old grandmother experiencing chest pain. Some emergency calls have a high potential for unexpected violence because people in an emergency situation might be afraid and react with anger. Patients, friends, family, or bystanders may direct their anger and rage toward you. Do not take this anger and frustration personally. More

important, do not become angry yourself because “anger feeds anger.”

When handling potentially violent situations, remain calm, reassuring, and gentle. Always be observant. Be aware of nonverbal clues, such as posture, position, and facial expressions. Look at the patient and be aware of how the patient is positioned. Is the patient stiff, with the hands clenched and feet wide apart?

If the scene is not safe or secured, then contact law enforcement to secure it. Never let a potentially violent or hostile patient leave the room alone. Understand that everything in reach of a patient has the potential to be used as a weapon.

Intoxication

The number of EMS calls dealing with a patient who is intoxicated has increased over the years. When you attempt to obtain a history for a patient who is intoxicated, be aware the information may not only be difficult to get, but also could be unreliable. Patients who are intoxicated may become impatient with you when they are trying to provide you with information. As their impatience increases, so does their anger level. Do not put patients in a position where they feel threatened and have no way out. As in other emergency cases, the potential for violence and a physical confrontation is high when a patient is intoxicated.

During the assessment and treatment of a patient who is under the influence, be accepting, diplomatic, objective, and nonjudgmental. Because of the intoxication, patients may not be telling you everything about how they feel. Alcohol dulls a patient's senses, which will make it difficult for patients who are intoxicated to inform you that something feels painful. Treat all patients with dignity and respect. Never assume their condition is the result of alcohol consumption when an underlying medical condition or trauma may be the cause of the problem.

Crying

A crying patient is a breathing patient. But why do some patients cry? In the context of an emergency, a patient who cries may be sad, in pain, or emotionally overwhelmed. No matter the reason for crying, you need to remain calm, patient, reassuring and confident and maintain a soft voice.

Your presence may make a crying patient feel more secure. In some extreme cases, additional diplomacy and verbal intervention will help. No matter how you address a crying patient, as with all patients, be sympathetic and treat them with respect and dignity.

Depression

Depression is a common reason for patients to call EMS. In fact, according to the World Health Organization, depression is the leading cause of disability worldwide, with an estimated 264 million people of all ages suffering from this condition.⁴ Some of the symptoms of depression include sadness, a feeling of hopelessness, restlessness, and irritability. The patient may also have sleeping and eating disorders and a decreased energy level. Depression is a normal human response, but it can lead to harmful behavior. When you encounter a patient with depression, be nonjudgmental and compassionate toward the patient's feelings. The most effective pre-hospital approach to a patient's depression is being a good listener. Often, the patient needs someone to talk to and someone to listen.

Confusing Behavior or History

Patients sometimes provide more history information to hospital personnel than they do to AEMTs because they are embarrassed or frightened and may feel more comfortable talking with hospital staff. Whatever the situation, you must be aware of medical causes that can lead a patient to report a confusing history. Hypoxia, stroke, diabetes, trauma, and drug/medication use could alter a patient's explanation of events. One of the most common causes of confusion is hypoxia. It is not uncommon to encounter an older patient who has dementia, delirium, or Alzheimer disease. It is important to verify the baseline mental status of each patient. Do not assume that because a patient is older and confused, one of these conditions is necessarily present. (These conditions are discussed in more detail in Chapter 37, *Geriatric Emergencies*.)

Confused behavior is *not* a normal response. After you have properly assessed and treated any life threats, attempt to ask the patient again about the chief complaint or ask someone close to the patient, such as family members or friends, to provide additional details.

Street Smarts

An altered mental status in any patient should be considered abnormal until proven otherwise. Immediately consider hypoxia, hypoglycemia, head injury, or shock as potential culprits. Even patients with a history of dementia or alcohol intoxication may have hypoxia or hypoglycemia. Do a thorough assessment on every patient, and do not assume that an altered mental status is normal for anyone.

Limited Cognitive Abilities

Cognitive disabilities can range from those that are barely recognizable to those that are severe. Develop a habitual method for dealing with a patient who has limited cognitive abilities. First, assume you can get an adequate history. Keep your questions simple and limit the use of medical terms. Be alert for partial answers and keep asking questions. In cases in which patients have severely limited cognitive function, rely on family, caregivers, and friends to supply or supplement answers to your questions. See Chapter 4, *Communications and Documentation*, for more information about communication challenges and techniques.

Language Barriers

We live in a country that is a melting pot of people with diverse nationalities. Not everyone speaks English. For example, imagine that you respond to a call for an older woman who fell at a nursing home. The emergency response seems pretty straightforward until you ask the patient what happened and she answers in French. If you do not speak the language, then how will you ask the patient to describe what happened and what hurts? Keep in mind that some patients may have disabilities that make it difficult to understand them in any language.

To overcome language barriers, consider using interpreters, translation resources, and related mobile device apps. The best answer is to find an interpreter, but it is not always that simple. First, determine whether the patient speaks or understands any English by asking the patient or others who may be present. Start by introducing yourself by using your name. Determine whether the patient understands who you are. Patients who are able to

provide their name have the ability to understand some English, but more importantly, they have cognitive ability (the ability to understand). Remember that increasing the volume of your questions or of your voice will not increase the patient's understanding of what you are asking. Keep questions straightforward and brief. Simple is best. Use of hand gestures may be helpful.

Be aware of the diversity of languages present in your community. Some dispatch centers and most hospitals have set up programs within the institution that identify various employees who can speak different languages. Programs that provide interpreters through telehealth linkages are also available that essentially make translation services for all languages available at all times of the day. Provide the hospital with advanced notice that a non-English-speaking patient will be arriving. This practice will allow the hospital the opportunity to make necessary arrangements for an interpreter.

Hearing Impairments

Hearing disabilities in patients range from slight to total deafness. Hearing impairment can make the process of obtaining an in-depth history difficult. When you are treating a patient who has a hearing deficit, ask questions slowly and clearly. You may want to use a stethoscope to function like a hearing aid; have patients place the stethoscope in their own ears while you speak softly into the stethoscope bell, which will amplify the sound. Changing the pitch of your voice may also help the patient to hear you.

Street Smarts

Many mobile device apps are available to assist in communication with patients who are hard of hearing or who speak another language.

Often, a patient who has had a hearing disability for some time will have mastered the technique of reading lips. In a situation where you are required to wear a mask due to community prevalence of aerosolized transmission of disease, consider communicating outdoors, where physical distancing can avoid the need for a mask, to the extent that can be accomplished safely and effectively. If the patient has a hearing aid, then ask the patient to use

it. Speak slowly and face-to-face with the patient. Some patients will attempt to use sign language for communication, which can be difficult for others to understand. Learning simple sign language during your career will help in the communication process. Probably the simplest way to communicate with a patient who has a hearing deficit is to use a pencil and paper. Write down uncomplicated questions that require simple yes or no answers.

Visual Impairments

Identify yourself verbally when entering the home of a visually impaired patient who has called for help. By announcing yourself when entering a residence, you are letting a patient know that help has arrived and any response from the patient may help you locate the patient's whereabouts. If the patient cannot see clearly and has eyeglasses, then ask the patient to put them on.

During the assessment and subsequent treatment of a patient who is visually impaired, it is important that you put any items that have been moved back into their previous position. Many visually impaired patients can move freely about

their homes because they know exactly where everything is placed. If you move something, put it back.

During the assessment and history-taking process, explain to the patient what is happening and stay in contact with the patient by keeping a hand on the patient's arm or shoulder. Notify patients when you prepare to lift and move them on the stretcher or do anything to them. Remember, you are a stranger to the patient, and an EMS vehicle is a foreign environment. A little communication can go a long way in easing uncertainty in a visually impaired patient.

Words of Wisdom

Throughout your assessment process, take note of the patient's mental status. Changes in mental status will be your best indicator for improvement or deterioration in your patient's condition. If at any time deterioration in mental status or function occurs, then your immediate attention is required and the severity of your patient's condition should be upgraded.

Patient Assessment

Secondary Assessment

If the patient is in stable condition and has an isolated complaint, then the secondary assessment may occur at the scene. If the secondary assessment is not performed at the scene, then it is performed in the back of the ambulance en route to the hospital. However, in some situations, you may not have time to perform a secondary assessment, such as if you have to continually manage life threats that were identified during the primary survey.

The purpose of the **secondary assessment** is to obtain vital signs and perform a systematic physical exam of the patient. As part of the secondary

assessment, you will take a complete set of vital signs. At a minimum, assess and document the following:

- Level of consciousness
- Respirations
- Pulse
- Blood pressure
- Skin condition
- Blood glucose
- Pulse oximetry

The physical exam may be a head-to-toe, **full-body exam** or an exam that focuses on a certain area or region of the body, often determined through the chief complaint. Circumstances will dictate which aspects of the physical exam will be used.

Street Smarts

Patients may feel vulnerable and exposed during a physical exam. Display compassion during this difficult time, and clearly explain to your patient what you are doing. It is important to protect the patient's modesty and maintain body temperature by keeping areas covered that you are not currently assessing.

An integral part of your physical exam is to compare findings on one side of the body with the other side when possible. If one ankle appears swollen, then look at the other. If one shoulder feels “out of joint,” then feel the other one to compare. When listening to breath sounds, listen to both sides of the chest. Find out which conditions are new and which ones the patient has been experiencing for some time.

On some occasions, it may even be helpful to note odors during an exam. Odors can indicate anything from infections, to certain medical conditions, to scene safety threats.

Assess Vital Signs Using the Appropriate Monitoring Devices

The use of monitoring equipment in the prehospital setting has continued to expand. AEMTs at all levels use a wide variety of devices in the continuous monitoring of patients. It is important to remember that these devices are manufactured and subject to limitations and mechanical failures. Always follow the manufacturer's instructions for operating any device. These devices should never be used to replace your comprehensive assessment of your patient; think of these devices as simply adjuncts to the assessment and treatment of your patient. Obtaining and using information from patient monitoring devices includes, but is not limited to, data from pulse oximetry, noninvasive blood pressure monitoring, end-tidal carbon dioxide measurements, and blood glucose monitoring.

Pulse Oximetry

Pulse oximetry is an assessment tool that is used to evaluate the effectiveness of oxygenation. The pulse oximeter is a photoelectric device that monitors

FIGURE 10-28 The pulse oximeter is a device that measures the saturation of oxygen in the blood as a percentage.

© Juanrvelasco/Stock/Getty Images.

the oxygen saturation of hemoglobin (the iron-containing portion of the red blood cell to which oxygen attaches) in the capillary beds (**FIGURE 10-28**). The parts that make up the pulse oximeter include a monitor and a sensing probe. The sensing probe clips onto a finger or earlobe. The light source must have unobstructed access to a capillary bed, so dark fingernail polish might need to be removed. Results appear as a percentage on the display screen. Normally, pulse oximetry values in ambient air will vary depending on the altitude, with most values falling between 95% and 99%.

The goal of applying oxygen therapy is to increase oxygen saturation to a normal level. This device is a useful assessment tool to determine the effectiveness of oxygen therapy, bronchodilator therapy, and artificial ventilations. However, the pulse oximeter does not take the place of good assessment skills and should not prevent the application of oxygen to any patient who reports difficulty breathing, regardless of the pulse oximetry value seen on the monitor.

Because the device presumes adequate perfusion and numbers of red blood cells, any situation that causes vasoconstriction (such as hypothermia

Words of Wisdom

Always treat your patient, not the diagnostic tools! A patient with dyspnea needs oxygen regardless of the pulse oximeter readings.

or shock) or loss of red blood cells (such as bleeding or anemia) will result in inaccurate or misleading values. The device also presumes that oxygen is saturating the hemoglobin. Therefore, any chemical that displaces oxygen (such as carbon monoxide) will also cause misleading values.

The pulse oximeter is a useful tool as long as you remember that the device is only a tool, not a substitute for a good assessment. Do not rely on the device when hypoperfusion or known anemia is present, carbon monoxide or exposure to other toxic inhalants has occurred, or the patient's extremities are cold.

Noninvasive Blood Pressure Measurement

The sphygmomanometer, or blood pressure cuff, is used in the measurement of the patient's blood pressure (discussed later in this chapter). Blood pressure is a routine vital sign that should be continuously monitored. This device consists of an inflatable cuff that occludes blood flow and a manometer (pressure meter) that is used to determine the pressure in the artery at various points in the physical exam. These two components are connected via tubing. In manual cuffs, a separate tube connects to an inflation bulb. The auscultatory method (listening) is the most common means of measuring a patient's blood pressure using a sphygmomanometer. In contrast, blood pressure measured by palpation is accomplished by palpating the radial pulse as the cuff is deflated. Only a systolic measurement can be obtained by palpation.

Oscillometric measurement, or electronic measurement, is another method of obtaining blood pressure readings of patients. An electronic device measures changes in pressure oscillations that occur during cuff deflation and are related to systolic, mean, and diastolic pressures. Two types of electronic devices are used in the prehospital setting; the blood pressure cuff deflates differently in each device. The first device measures readings using linear deflation, and the second type measures readings by using stepped deflation. An electronic blood pressure cuff that uses linear deflation allows a uniform decline in pressure in the cuff during deflation. Conversely, stepped deflation allows the cuff to deflate in small steps or intervals. Although

both devices are accurate in the prehospital setting, stepped deflation tends to be more accurate in patients who are moving and in patients who may be hypotensive. Stepped deflation can release the pressure in the cuff in intervals at variable lengths, allowing the system to better detect oscillations. Always take the first set of vital signs manually, regardless of the availability of electronic devices.

Electronic devices are prone to inaccurate readings in moving vehicles, noisy environments, or if the cuff is not correctly sized or properly placed on the patient. If you are faced with readings that do not match the clinical presentation of the patient, then obtain manual readings to confirm.

Street Smarts

Ask patients if they know their normal pulse or blood pressure. Many people monitor heart rate with a smart watch and can readily provide this information. Very fit people and those taking medicines such as beta-blockers may have a normal resting heart rate of less than 60 beats per minute. Likewise, a patient may normally have an average blood pressure that is either very high, or runs less than 90 mm Hg systolic. This baseline information helps you gauge whether the values you are finding are normal for this person.

End-Tidal Carbon Dioxide

Although pulse oximetry can evaluate the effectiveness of oxygenation, it cannot measure the amount of oxygen being consumed by a patient's cells during cellular metabolism. To determine oxygen consumption, you will need to measure **carbon dioxide (CO₂)** levels. CO₂ is the by-product of aerobic cellular metabolism and reflects the amount of oxygen being consumed during the process. Metabolism refers to the chemical reactions that occur in the body or cells to maintain life. The two noninvasive methods by which CO₂ is monitored in the field are capnometry and capnography. **Capnometry** typically consists of a disposable or electronic device that provides you with a means of measuring CO₂ output. **Capnography** includes not only a measurement of CO₂ output, but also provides a waveform based on serial measurements (**FIGURE 10-29**). Capnography can quickly and efficiently provide

FIGURE 10-29 This device is capable of monitoring multiple functions simultaneously, including continuous capnography (bottom tracing).

information about a patient's ventilatory status, circulation, and metabolism. Capnography also serves as an indicator of chest compression effectiveness and can detect return of spontaneous circulation. The provision of this information is possible because blood must circulate through the lungs for CO_2 to be exhaled and measured. These devices are typically used in the prehospital setting as a secondary means to verify endotracheal tube placement, to maximize a patient's ventilatory status, and to avoid inadvertent hyperventilation of patients with head injuries, which has been linked to poor outcomes.

End-tidal carbon dioxide (ETCO_2) is the partial pressure or maximal concentration of CO_2 at the end of an exhaled breath, which is expressed as a percentage of CO_2 , or in millimeters of mercury (mm Hg). Thus, digital display of ETCO_2 is expressed in mm Hg or as a percentage of CO_2 . The normal range is 35 to 45 mm Hg, or 5% to 6% CO_2 . Because CO_2 is not present in the esophagus, use of an ETCO_2 detector is a reliable (and essential) method for confirming and monitoring advanced airway placement. When capnography shows an absence of CO_2 , it may indicate the endotracheal tube is in the wrong position or there is an absence or decrease in the level of CO_2 in the lungs—possibly from cardiac arrest, ineffective CPR, or shock. When cardiac output increases, the ETCO_2 measurement

FIGURE 10-30 Colorimetric capnographers.

Courtesy of Marianne Gausche-Hill, MD, FACEP, FAAP.

provides information on the adequacy of ventilation and circulation.

ETCO_2 is measured or detected by colorimetry, capnometry, and capnography devices. **Colorimetric devices** come in different shapes and sizes but provide continuous end-tidal monitoring by displaying one of three colors (**FIGURE 10-30**). A colorimetric capnograph provides qualitative (that is, it does not assign a numeric value) information regarding the presence of CO_2 in the patient's exhaled breath. It does not measure the exact amount of CO_2 exhaled, but it indicates whether CO_2 is present in reasonable amounts in the exhaled breath of a patient. The device is attached between the advanced airway and bag-mask device. After six to eight positive-pressure ventilations—the amount of time it takes for CO_2 to accumulate in the device—the specially treated paper inside the detector should turn from purple to yellow during

Words of Wisdom

A colorimetric capnograph is a "spot-check" device that should be used during initial confirmation of advanced airway placement and then replaced as soon as possible with a quantitative device. The monitor may be incorrect (or fooled) if the patient has CO_2 trapped in the stomach from the ingestion of carbonated beverages, so confirm the reading over at least six breaths to be certain it is not a false-positive reading.

exhalation, indicating the presence of exhaled CO₂. Purple indicates a CO₂ level of less than 0.5%, tan indicates a range of 0.5% to 2%, and yellow indicates a level of greater than 2%. A yellow reading indicates adequate circulation. Remember to check these devices regularly for damage, cracks, and blockages caused by gastric secretions because this damage will affect the accuracy of the readings. Colorimetric devices are also sensitive to temperature extremes and humidity.

Blood Glucometry

The glucometer is used to measure the level of glucose in a patient's bloodstream. If the blood glucose level is low, then this finding can help you identify the reason a patient has a decreased LOC or is unresponsive. If the blood glucose level is high in a patient with nausea, vomiting, abdominal pain, and a change in mental status, then it may signal dangerous complications of high blood glucose.

Although determining glucose levels is largely a routine part of the patient assessment process, indications include known diabetes in patients with a decreased LOC, a decreased LOC of unknown origin in any patient, general malaise, weakness, or a poor general impression.

Most glucometers operate in much the same manner; however, refer to the manufacturer's instructions for the specific device being used. To obtain a measurement, you will need to use a lancet needle to obtain a drop of blood. Follow the steps in **SKILL DRILL 10-2** to assess blood glucose level.

There is only a small difference in the blood glucose results when samples are taken from capillary or venous sources. Samples may be obtained from the intravenous (IV) catheter when inserting an IV catheter rather than sticking the patient's finger. A normal glucose level is 80 to 120 mg/dL. Refer to Chapter 21, *Endocrine and Hematologic Emergencies*, for further information and treatment of endocrine conditions.

Like most mechanical devices, the glucometer may fail. Lack of calibration is a common problem for incorrect readings or failure of the device to work. Glucometers also have a set limit and will just read "Hi" above certain levels. Verify that the test strips match the glucometer you are using and are not expired. Most have a shelf life after opening as well, so write the date on the bottle label when it

is initially opened. Be familiar with the user manual for the device you are using, and refer to it as needed.

Systematically Assess the Patient: Full-Body Exam

The goal of the full-body exam is to identify hidden injuries or identify causes that may not have been found during the 60- to 90-second rapid exam that took place during the primary survey. Any patient who has sustained a significant MOI, is unresponsive, or is in critical condition should receive this type of exam after life threats have been managed and generally after transport has been initiated. An unresponsive patient is unable to tell you what is wrong; therefore, this type of exam may give you clues to identify the problem.

To perform a full-body exam of a patient with no suspected spinal injuries, follow the steps in **SKILL DRILL 10-3**. To perform a full-body exam in which the patient has sustained significant trauma, ensure manual stabilization is still in place and follow the steps in Skill Drill 10-3.

Words of Wisdom

Medical Assessment Versus Trauma Assessment

Any patient with a significant MOI or an altered mental status who cannot identify a specific complaint should receive a full head-to-toe assessment or full-body exam. The assessment of a patient without a traumatic injury who has a specific complaint should focus on the body system specific to the complaint.

Systematically Assess the Patient: Focused Assessment

A **focused assessment** is generally performed on patients who have sustained nonsignificant MOIs and on responsive medical patients with a specific complaint. This type of exam is based on the chief complaint. Your assessment can focus on a specific body part or system that has been affected. For example, in a person reporting a headache, carefully and systematically assess the head and/or the

Skill Drill 10-2 Assessing Blood Glucose Level

Step 1

Take standard precautions. Select, check, and assemble the equipment (glucometer, test strip, needle or spring-loaded puncture device, alcohol prep pads). Turn on the glucometer and insert a test strip. Cleanse the fingertip with an alcohol prep pad.

Step 2

Puncture the prepped site with lancet needle or puncture device, drawing capillary blood. Place blood on the test strip.

Step 3

Dispose of the lancet needle in a sharps container.

Step 4

Insert the test strip into the glucometer and activate the device per the manufacturer's instructions, applying the blood sample to the test strip when indicated.

Step 5

Dress the fingertip wound with pressure and an alcohol prep pad, then place a bandage over the puncture site. Record the reading from the glucometer and document appropriately.

Skill Drill 10-3 Performing the Full-Body Exam**Step 1**

Examine the face for obvious lacerations, bruises, and deformities. Maintain manual stabilization if spinal injury is suspected.

**Step 2**

Inspect the area around the eyes and eyelids.

**Step 3**

Examine the eyes for redness and for contact lenses. Assess pupils using a penlight.

**Step 4**

Look behind the ears to assess for bruising (Battle sign).

**Step 5**

Use the penlight to look for drainage of spinal fluid or blood in the ears.

**Step 6**

Examine the head for bruising and lacerations. Palpate for tenderness, depressions of the skull, and deformities.

Skill Drill 10-3 Performing the Full-Body Exam (*continued*)**Step 7**

Palpate the zygomas (cheekbones) for tenderness or instability.

**Step 8**

Palpate the maxillae.

**Step 9**

Check the nose for blood and drainage.

**Step 10**

Palpate the mandible.

**Step 11**

Assess the mouth and nose for cyanosis, foreign bodies (including loose teeth or dentures), bleeding, lacerations, and deformities.

**Step 12**

Check for unusual odors on the patient's breath.

(continues)

Skill Drill 10-3 Performing the Full-Body Exam (*continued*)**Step 13**

Inspect the neck for obvious lacerations, bruises, and deformities. Observe for jugular venous distention and/or tracheal deviation. Apply a cervical collar if spinal injury is suspected.

**Step 14**

Palpate the front and the back of the neck for tenderness and deformity.

**Step 15**

Inspect the chest for obvious signs of injury before you begin palpation. Watch for movement of the chest with respirations. Assess the work of breathing.

**Step 16**

Gently palpate over the ribs to elicit tenderness. Avoid pressing over obvious bruises and fractures.

**Step 17**

Listen for anterior breath sounds over the major airways (midaxillary and midclavicular lines).

Skill Drill 10-3 Performing the Full-Body Exam (*continued*)**Step 18**

Listen also to posterior breath sounds over the lower lungs (bases) and upper lungs (apices). At this point, also assess the back for tenderness and deformities, so that you log roll the patient only once. Remember, if you suspect a spinal cord injury, then use spinal precautions as you log roll the patient.

**Step 19**

Look at the abdomen and pelvis for obvious lacerations, bruises, and deformities. Gently palpate the abdomen for tenderness. If the abdomen is unusually tense, then describe the abdomen as rigid.

**Step 20**

Gently compress the pelvis from the sides to assess for tenderness.

**Step 21**

Gently press the iliac crests to elicit instability, tenderness, and/or crepitus.

**Step 22**

Inspect all extremities for lacerations, bruises, swelling, deformities, and medical alert anklets or bracelets. Also assess distal pulses and motor and sensory function in all extremities.

TABLE 10-4 Common Chief Complaints and Focused Assessments

Chief Complaint	Focused Assessment
Chest pain	Evaluate skin, pulse, and blood pressure. Look for trauma to the chest, assess the external jugular veins, and listen to breath sounds. Assess for peripheral/dependent edema.
Abdominal pain	Evaluate skin, pulse, and blood pressure. Look for trauma to the abdomen, and palpate the abdomen for tenderness or rigidity.
Shortness of breath	Evaluate skin, pulse, blood pressure, and rate and depth of respirations. Assess for airway obstruction or signs of distress such as accessory muscle use. Listen carefully to breath sounds, and assess for hypoxemia (that is, use pulse oximetry). Assess for peripheral/dependent edema.
Dizziness	Evaluate skin, pulse, blood pressure, and adequacy of respirations. Monitor the LOC and orientation carefully. Check the head for signs of trauma. Evaluate for signs of stroke, including facial droop, slurred speech, and one-sided weakness. Use a glucometer to assess blood glucose levels.
Pain associated with bones or joints	Evaluate skin, pulse, movement, and sensation adjacent and distal to the affected area.

Abbreviation: LOC, level of consciousness

© Jones & Bartlett Learning.

neurologic system. A person with a laceration on the arm may need to only have that arm evaluated. The goal of a focused assessment is to focus your attention on the immediate problem. **TABLE 10-4** gives examples of common chief complaints and the corresponding focused assessment.

Words of Wisdom

Not all patients who have edema will present with pedal edema. When you assess for dependent edema, remember that edema collects in the dependent or lowest areas of the body. For a patient who is bedridden, this area may be the sacral region of the back.

Respiratory System

You identified and managed life threats during the primary survey. During the secondary assessment, you will perform an exam to help determine which treatment to perform and protocols to follow when the patient’s chief complaint is focused on the respiratory system.

Look again for signs of airway obstruction and trauma to the neck and/or chest. Expose the patient’s chest, and inspect for overall symmetry. Does

the right side of the chest look like the left side? Listen carefully to breath sounds, noting abnormalities. Measure the respiratory rate, chest rise and fall (for tidal volume), and effort. Look for retractions. Is the patient using accessory muscles to help with breathing, and is increased work of breathing present?

Because the location of this complaint is the chest, carefully reevaluate the pulse rate and skin and blood pressure (described in the next section). Inspect and palpate from the clavicles to the shoulder to the abdomen, and reassess breath sounds. Note the presence of subcutaneous emphysema and any abnormalities found, and document those findings on the patient care report. With this information, you can develop a treatment plan and prioritize transport procedures.

Respiratory Rate

As mentioned previously, normal resting respiratory rate varies widely in adults, ranging from approximately 12 to 20 breaths/min. Children breathe at even faster rates. With practice, you will be able to estimate the rate and note whether it is too fast or too slow. Count the number of respirations during your primary survey if you do not feel comfortable with your estimation.

Respirations are determined by counting the number of breaths in a 30-second period and multiplying by two, counting the number of breaths in a 15-second period and multiplying by four, or counting the number of breaths for a full 60 seconds. The result equals the number of breaths per minute. For accuracy, count each breath at the same point in its cycle. This is most easily done by counting each peak chest rise. Although you can see peak chest rise, it is easier to place your hand on the patient's chest and feel it. However, be aware that responsive patients who know that you are evaluating their breathing will often override the automatic rate and depth by breathing more slowly and deeply. To prevent this from happening, check respirations in a responsive, alert patient without making the patient aware of what you are evaluating. This can be easily done by first taking a radial pulse and then, without releasing the wrist or otherwise suggesting a change, counting the chest rise that you see or feel as the patient's forearm rises and falls with the movement of the chest (**FIGURE 10-31**). If the patient coughs, yawns, sighs, or talks during the 30-second

FIGURE 10-31 Assess respirations in a responsive patient by first taking a radial pulse and then, without releasing the patient's wrist, counting the chest rise and fall for 30 seconds.

© Jones & Bartlett Learning.

period, then wait a few seconds and start again. **TABLE 10-5** shows the normal range of respiratory rates of patients who are at rest, as well as normal ranges for other vital signs at various ages.

YOU are the Provider

Part 4

A cervical collar is applied and the decision is made to remove the patient with a vest-type extrication device. Firefighters who have arrived on scene prepare the stretcher and backboard. With the assistance of your partner and a firefighter, you are able to rotate the patient onto the backboard and properly secure her. Pulse, motor, and sensation are reassessed with no change. A quick reassessment determines that the patient is alert and oriented, but does not remember the crash. Respirations and radial pulses are normal and skin is still warm and dry. A quick check of her blood glucose shows 98 mg/dL. The patient is placed in the ambulance and transported to the local trauma center. Reassessment continues and a single 18-gauge IV line is started en route. Radiographs show that the patient has an unstable fracture of her sixth cervical vertebra, and the trauma surgeon commends you on a job well done protecting the spine during extrication and transport.

Recording Time: 15 Minutes

Respirations	16 breaths/min; clear
Pulse	88 beats/min
Skin	Warm and dry
Blood pressure	116/84 mm Hg
Oxygen saturation (SpO₂)	99% on oxygen at 15 L/min
Pupils	PERRLA

7. How often should you reassess your patients?
8. Why is critical thinking important as an AEMT?

TABLE 10-5 Normal Vital Signs at Various Ages

Age	Pulse Rate (beats/min)	Respirations (breaths/min)	Blood Pressure (mm Hg)	Temperature (°F)
Neonate (0 to 1 month)	Awake: 100 to 205 Asleep: 90 to 160	30 to 60	Systolic: 67 to 84 Diastolic: 35 to 53 Mean arterial pressure: 45 to 60	98 to 100 (37 to 38°C)
Infant (1 month to 1 year)	Awake: 100 to 180 Asleep: 90 to 160	30 to 53	Systolic: 72 to 104 Diastolic: 37 to 56 Mean arterial pressure: 50 to 62	96.8 to 99.6 (36 to 37.5°C)
Toddler (1 to 2 years)	Awake: 98 to 140 Asleep: 80 to 120	22 to 37	Systolic: 86 to 106 Diastolic: 42 to 63 Mean arterial pressure: 49 to 62	96.8 to 99.6 (36 to 37.5°C)
Preschooler (3 to 5 years)	Awake: 80 to 120 Asleep: 65 to 100	20 to 28	Systolic: 89 to 112 Diastolic: 46 to 72 Mean arterial pressure: 58 to 69	98.6 (37°C)
School-age child (6 to 12 years)	Awake: 75 to 118 Asleep: 58 to 90	18 to 25	Systolic: 97 to 120 Diastolic: 57 to 80 Mean arterial pressure: 66 to 79	98.6 (37°C)
Adolescent (12 to 17 years)	Awake: 60 to 100 Asleep: 50 to 90	12 to 20	Systolic: 110 to 131 Diastolic: 64 to 83 Mean arterial pressure: 73 to 84	98.6 (37°C)
Early adult (18 to 40 years)	60 to 100	12 to 20	Systolic: 90 to 140	98.6 (37°C)
Middle adult (41 to 60 years)	60 to 100	12 to 20	Systolic: 90 to 140	98.6 (37°C)
Older adult (61 years and older)	60 to 100	12 to 20	Systolic: 90 to 140	98.6 (37°C)

Pediatric data from: American Heart Association (AHA). Vital signs in children. Pediatric Advanced Life Support; Dallas, TX: AHA; 2020.

Words of Wisdom

Automated blood pressure machines often display mean arterial pressure (MAP) in addition to systolic and diastolic blood pressures. The MAP is a measure of the average arterial pressure through the systolic and diastolic phases of the cardiac cycle. It is increasingly used as a valuable measurement to determine perfusion in conditions such as sepsis. A MAP of greater than 60 is needed to adequately perfuse the vital organs in an adult.

Respiratory Rhythm

While counting the patient's respirations, also note the rhythm. If the time from one peak chest rise to the next is fairly consistent, then respirations are considered regular. If respirations vary or change frequently, then they are considered irregular. When you document the vital signs, be sure to note whether the patient's respirations were regular or irregular.

Quality of Breathing

It is helpful to quickly listen to breath sounds on each side of your patient's chest early in the primary

survey. This step can help identify the quality of air movement in both lungs. Decreased or absent breath sounds on one side of the chest and decreased movement in the rise and fall on one side indicate inadequate breathing.

TABLE 10-6 shows four ways in which the quality or character of respirations can be described. You can determine the quality or character of respirations while you are counting the number of respirations. Use your sense of hearing to listen for breath sounds or use the preferred method of auscultation, listening with a stethoscope.

Normal breathing is silent or, in a quiet environment, accompanied only by the sounds of air movement at the mouth and nose. Through a stethoscope, normal breath sounds include only the sound of air movement through the bronchi accompanied by a soft, low-pitched murmur. Breathing accompanied by other sounds may indicate a significant respiratory condition. If the upper airway has a mild obstruction caused by a foreign body or swelling, then you may hear stridor. If you can hear bubbling or gurgling in the upper airway, then the patient probably has fluid in those passages, potentially impeding the exchange of gases. Suction the patient to avoid **aspiration** of fluid into the lungs. A mild upper airway obstruction is usually a result of the tongue blocking the airway in unresponsive patients. You may hear other sounds, like wheezes or snoring, or a musical sound indicative of a mild lower airway

obstruction. The presence of any of these abnormal sounds indicates that an airway or breathing problem exists. With a severe airway obstruction, the patient will not be able to move any air and will no longer be able to cough or talk. Sounds are caused by air moving through small spaces or fluid. If you hear no sounds, then the patient may be moving no air and requires treatment to clear the obstruction.

The following describes how and where to listen to assess breathing:

- First, remember that you can almost always hear a patient's breath sounds better from the patient's back; therefore, if the patient's back is accessible, auscultate (listen) there. If you have stabilized the patient on a backboard or if the patient is in a supine position, then listen from the front and sides (**FIGURE 10-32**).

A

B

FIGURE 10-32 A. Listen to breath sounds from the patient's back (if possible), over the apices, the midlung fields, and the bases. **B.** If the patient is immobilized on a backboard or in a supine position, then listen from the front and sides.

TABLE 10-6 Characteristics of Respirations

Normal (eupneic)	Breathing is neither shallow nor deep Equal chest rise and fall No use of accessory muscles
Shallow	Decreased chest or abdominal wall motion
Labored	Increased breathing effort Use of accessory muscles Possible gasping Nasal flaring, supraclavicular and intercostal retractions in infants and children
Noisy	Increase in sound of breathing, including snoring, wheezing, gurgling, crowing, grunting, and stridor

- Auscultate over the upper lungs (apices) at approximately 1 inch (2.5 cm) below the clavicle at the midclavicular line, the midlung fields at the third or fourth intercostal space from the patient's posterior, and the lower lungs (bases) at the sixth intercostal space, midaxillary line.
- Lift the clothing or slide the stethoscope under the clothing. When you listen over clothing, you will primarily hear the sound of the stethoscope sliding over the fabric because breath sounds are muted by clothing.
- Place the diaphragm of the stethoscope firmly against the skin to hear the breath sounds.

During your assessment, you may be able to identify normal breath sounds or **adventitious sounds** (abnormal sounds). Adventitious sounds include crackles, rhonchi, stridor, wheezing, and pleural friction rubs. Breath sounds are described as follows:

- **Normal breath sounds.** These sounds are clear and relatively quiet during inspiration and expiration. Tracheal sounds (noted over the trachea) are loud and harsh. The loud, high-pitched, and hollow sounds noted over the manubrium (over the main stem bronchus) are known as bronchial sounds. The soft, breezy, lower pitched sounds found at the midclavicular line are known as **bronchovesicular sounds**. The finer and somewhat fainter breath sounds noted in the lateral wall of the chest are from the smaller bronchioles and alveoli and are known as **vesicular sounds**.
- **Wheezing.** These sounds suggest an obstruction or narrowing of the lower airways. Wheezing is a high-pitched whistling sound that is most prominent on expiration, but can also be heard on inspiration in sicker patients. If wheezing is unilateral, then suspect an aspirated foreign body or infection. If wheezing is bilateral, then an inhaled irritant such as chlorine or disease states such as reactive airway disease, asthma, or other less common lung diseases (such as asbestosis) may be the problem.
- **Crackles.** Wet breath sounds may indicate cardiac failure or infection, especially in a young child. Such sounds are often difficult to hear, especially in the back of a moving ambulance. A moist crackling, usually on inspiration and

expiration, is called crackles (formerly called rales). Crackles are produced by air passing through moisture in the bronchoalveolar system or by closed alveoli opening abruptly.

- **Rhonchi.** Rhonchi, or congested breath sounds, are continuous sounds with a lower pitch and a rattling quality and are indicative of fluid in the larger airways in the lungs. Rhonchi may indicate the presence of mucus in the lungs, for example, as a result of an infection (such as pneumonia) or inflammation (such as bronchitis). Expect to hear low-pitched, noisy sounds that are most prominent on expiration. The patient often reports a productive cough associated with these sounds. Aspiration of fluid may also result in rhonchi.
- **Stridor.** Stridor is a brassy, crowing sound often heard without a stethoscope. It is caused by the narrowing, swelling, or obstruction of the upper airway and may indicate that the patient has an airway obstruction in the neck or upper part of the chest. It is most prominent on inspiration. Stridor may be caused by bacterial epiglottitis, viral croup, swelling from upper airway burns, anaphylaxis, or a partial foreign body airway obstruction. Onset of crowing or stridor in the presence of fever or upper respiratory infection should be recognized as a potential threat to life.
- **Pleural friction rub.** This squeaking or grating sound occurs when the pleural linings rub together. This sound means the pleural layers have lost their lubrication, most commonly caused by inflammation of the pleura. This condition is usually associated with pain on inspiration. The sounds may be heard any time the chest wall moves; therefore, they can be heard on inspiration, expiration, or both.

A patient who coughs up thick, yellow or green sputum (matter from the lungs) most likely has an advanced respiratory infection. A patient with a chest injury may cough up blood or frothy white or pink sputum caused by blood and fluid mixing with air in the lungs. A patient with heart failure may also cough up frothy sputum. The presence of either substance, regardless of its cause, indicates that an urgent, potentially critical cardiovascular and respiratory problem may exist, possibly requiring oxygenation, ventilation, and other treatments.

Without these treatments, the patient's condition may deteriorate rapidly to a point where the patient can no longer breathe.

Depth of Breathing

The amount of air that the patient is exchanging depends on the rate and the tidal volume. **Tidal volume** is a measure of the depth of breathing and is the amount of air in milliliters that is moved into or out of the lungs during one breath. The depth of the breath determines whether the tidal volume is normal, less than normal, or more than normal. Normal tidal volume for an adult is approximately 500 mL or 7 mL/kg per breath. Shallow respirations indicate a decreased tidal volume, and deep respirations indicate an increased tidal volume.

Cardiovascular System

When the patient's chief complaint is associated with chest pain or other discomfort, a physical exam should include looking, listening, and feeling for abnormalities in the patient's thoracic region. Listen for breath sounds and look for trauma to the chest. Consider the pulse and respiratory rate and the blood pressure. Pay particular attention to rate, quality, and rhythm of the pulse. Reevaluate the skin. Check and compare distal pulses to determine any differences in the right and left sides. Consider auscultation for abnormal heart tones, such as those that are muffled; however, keep in mind that obtaining these sounds may be difficult in a noisy prehospital setting.

Pulse Rate

For an adult, the normal resting pulse rate should be between 60 and 100 beats/min and may remain on the higher end of normal in older patients. Generally, in pediatric patients, the younger the patient, the faster the pulse rate. In well-conditioned athletes or in people taking heart medications such as beta-blockers, the pulse rate may be considerably lower. See Table 10-5 for the normal ranges of pulse rates for adults and children.

To obtain the pulse rate in most patients, count the number of pulses felt in a 30-second period and then multiply by two, count the number of pulses felt in a 15-second period and multiply by four, or count the number of pulses for a full 60 seconds. A pulse that is weak and difficult to palpate, irregular,

or extremely slow should be palpated and counted for a full minute. A pulse rate is counted as beats per minute; however, in reporting the pulse rate, it is not necessary to state or write "beats per minute" after the number.

In an adult patient, a pulse rate that is greater than 100 beats/min is described as **tachycardia**, and a rate of less than 60 beats/min is described as **bradycardia**.

Pulse Quality

Always report the quality, or character, of the pulse whenever reporting or recording the pulse. The pulse is generally palpated at the radial or carotid artery in adults and at the brachial artery in infants, because it is normally strong and easily palpable at these locations. Therefore, if the pulse feels of normal strength, describe it as being strong. Describe a stronger than normal pulse as "bounding" and a pulse that is weak and difficult to feel as "weak" or "thready." With a little experience, you will be able to easily make the necessary distinctions.

Pulse Rhythm

When you are assessing the pulse, you must also determine whether the rhythm is regular or irregular. When the interval between each ventricular contraction of the heart is short, the pulse is rapid. When the interval is longer, the pulse is slower. Regardless of the rate, the interval between each contraction should be the same, and the pulse should occur at a constant, regular rhythm. Document this rhythm as regular.

The rhythm is considered irregular if the heart periodically has an early or late beat or if a pulse beat is missed. Some people have a chronically irregular pulse; however, if an irregular pulse is found in a patient with signs and symptoms that suggest a cardiovascular condition, the patient likely needs advanced cardiac assessment and life support. Therefore, depending on your protocols, call for paramedic backup or initiate rapid transport to definitive care.

With practice, you will be able to assess whether the pulse is too slow, too fast, or irregular without actually counting the pulsations. This will help to speed your assessment of the ABCDEs and allow you to focus on finding other potentially life-threatening problems. A pulse rate that is too slow

or too fast may influence decisions related to treating and transporting your patient.

Blood Pressure

Adequate blood pressure is necessary to maintain proper circulation and perfusion of the vital organs. **Blood pressure** is the pressure of circulating blood against the walls of the arteries. A decrease in the blood pressure may indicate one of the following:

- Loss of blood or its fluid components
- Loss of vascular tone and sufficient arterial constriction to maintain the necessary pressure even without any actual fluid or blood loss
- A cardiac pumping problem
- An overdose of a beta-blocker or other antihypertensive medication

When any of these conditions occurs and results in a decrease in circulation, the body's compensatory mechanisms are activated, resulting in an increased heart rate and constriction of the arteries. Normal blood pressure is maintained, and by decreasing the blood flow to the skin and extremities, available blood volume is temporarily redirected to the vital organs so that they remain adequately perfused. However, as shock progresses, and the body's defense mechanisms can no longer keep up, the blood pressure will fall. Decreased blood pressure is a late sign of shock and indicates that the patient is in the critical phase of decompensated shock unless the patient is experiencing neurogenic (or spinal) shock. Any patient with a markedly low blood pressure has inadequate pressure to maintain proper perfusion of all of the vital organs and needs that blood pressure and perfusion restored immediately to a normal level.

When the blood pressure becomes elevated, the body's defenses act to reduce it. Some people have chronically high blood pressure from progressive narrowing of the arteries that occurs with age, and during an acute episode, their blood pressure may increase to even higher levels. Head injury or a number of other conditions may also cause blood pressure to rise to high levels. Abnormally high blood pressure may result in a rupture or other critical damage to the arterial system.

Blood pressure contains two key separate components: systolic pressure and diastolic pressure. **Systolic pressure** is the increased pressure that is caused along the artery with each contraction

(systole) of the ventricles and the pulse wave that it produces. This is the pumping, or working, phase of the heart. **Diastolic pressure** is the residual pressure that remains in the arteries during the relaxing phase of the cycle of the heart (diastole), when the left ventricle is at rest. This is the resting phase, and it should be significantly lower than the systolic pressure. Systolic pressure represents the maximum pressure to which the arteries are subjected, and the diastolic pressure represents the minimum amount of pressure that is always present in the arteries.

Early blood pressure gauges contained a column of mercury and a linear scale that was graduated in millimeters. Even though different gauges are used today, the blood pressure is still measured in millimeters of mercury (mm Hg). Blood pressure is reported as a fraction in the form of systolic pressure over diastolic pressure. Therefore, if the patient's systolic pressure is 120 and the diastolic pressure is 78, then you would record it as "BP 120/78 mm Hg." You would report the patient's blood pressure verbally as "BP is 120 over 78."

Avoid taking a blood pressure on an arm if the patient has an IV site, a central line catheter, or a port; has a dialysis fistula or shunt; has had a mastectomy on that side; or has an injury to that arm. You can ask the patient if any of these exist if they are not visible—for example, a mastectomy. If a patient has chronic renal failure and is undergoing dialysis, then you may ask if the patient has a fistula or any other reason that you should not take a blood pressure using that arm.

A blood pressure cuff with gauge (sphygmomanometer) contains the following components (**FIGURE 10-33**):

- A wide outer cuff designed to be fastened snugly around the entire arm or leg
- An inflatable wide bladder sewn into a portion of the cuff
- A ball-pump with a one-way valve that allows air to enter and a turn-valve that can be closed or, when opened, will allow air to be released at a controlled speed from the cuff
- A pressure gauge calibrated in millimeters of mercury, which indicates the pressure that exists in the cuff that is being applied against the underlying artery

Most EMS agencies carry at least four sizes of blood pressure cuffs: obese, adult, pediatric, and

FIGURE 10-33 A sphygmomanometer.

© WizData, Inc./Shutterstock.

FIGURE 10-34 Blood pressure cuffs: thigh, adult, and pediatric.

© Jones & Bartlett Learning.

infant (**FIGURE 10-34**). A thigh cuff is also available. Be sure to select the appropriate-size cuff. A cuff that is too small may result in falsely high readings; a cuff that is too large may result in falsely low readings. The normal size cuff is designed to wrap around the arm 1 to 1.5 times and take up two-thirds the length from the armpit to the crease in the elbow of most adults. Use an obese or thigh cuff with patients who are obese or have exceptionally well-developed arm muscles, and to take the blood pressure in the thigh in patients who have injuries in both arms. Use a small pediatric cuff with children and exceptionally small adults. Measure the blood pressure in all patients older than 3 years.

The auscultatory method (listening) is the most common means of measuring a patient's blood pressure. A blood pressure cuff is applied to a patient's upper arm, allowing for the compression of

the brachial artery when inflated. This compression creates turbulence and arterial vibrations that make sounds that can be heard using a stethoscope. These sounds are known as Korotkoff sounds. As the cuff is released, the blood flow returns to the artery, and Korotkoff sounds will be heard, denoting the systolic pressure. The disappearance of Korotkoff sounds indicates the diastolic pressure reading.

Follow the steps in **SKILL DRILL 10-4** to measure blood pressure by auscultation.

Words of Wisdom

Blood pressure is most often measured by auscultation with the patient in a sitting or semisitting position. Be sure to note whether a different method or position was used. Occasionally when a patient's blood pressure is very low, you will continue to hear pulse sounds from the reading at which they started all the way until the gauge has reached 0. When this occurs, record the diastolic pressure as "0" or "all the way down" to indicate that pulse sounds were heard until the gauge read "0."

Obtaining a patient's blood pressure accurately by auscultation may be difficult at times. Noisy environments, patient movement from tremors or seizures, external vibrations from the EMS vehicle, and excessive noises may produce sounds that mimic Korotkoff sounds and provide inaccurate readings. Other variables that may make obtaining an accurate blood pressure reading nearly impossible are uncooperative adults, infants and children, and patients who are hypotensive with poor perfusion. In these cases, measure blood pressure by palpation.

The palpation (touch) method does not depend on your ability to hear sounds and should be used in these cases to obtain a patient's blood pressure. If possible, then it is preferable that you first obtain a baseline auscultated blood pressure. Follow the steps in **SKILL DRILL 10-5** to measure blood pressure by palpation.

Normal Blood Pressure

Blood pressure levels vary with age and sex. Refer to Table 10-5 for normal blood pressure ranges.

A patient has **hypotension** when the blood pressure is lower than the normal range and **hypertension** when the blood pressure is higher than the normal range.

Skill Drill 10-4 Obtaining Blood Pressure by Auscultation

Step 1

Take standard precautions. Check for ports, central lines, mastectomy, dialysis fistula, and injury to the arm. If any are present, then use the brachial artery on the other arm. Apply the cuff snugly. The lower border of the cuff should be about 1 inch (2.5 cm) above the antecubital space (the crease at the inside of the patient's elbow). Ensure the center of the inflatable bladder, which is usually marked by an arrow on the cuff, lies over the brachial artery.

Step 2

Support the exposed arm at the level of the heart. With your nondominant hand, palpate the brachial artery (in the antecubital fossa, the anterior aspect of the elbow) to determine where to place the stethoscope.

Step 3

Place the bell (if one is present) of the stethoscope over the brachial artery, and hold it firmly against the artery with the fingers of your nondominant hand. Hold the rubber ball-pump in the palm of your other hand and the turn-valve between your thumb and first finger.

Step 4

Close the valve tightly, and pump to 30 mm Hg above the point at which you stop hearing pulse sounds. Next, slowly turn the valve, opening it until air is steadily escaping from the cuff and you see the needle of the gauge slowly drop. The systolic pressure is the first time you hear the Korotkoff sound. The diastolic pressure is the last time it is heard.

Step 5

As soon as the pulse sounds stop, open the valve, and quickly release remaining air. After you have finished measuring the blood pressure, document your findings and the time at which the blood pressure was taken.

Skill Drill 10-5 Obtaining Blood Pressure by Palpation

Step 1

Secure the appropriate-size cuff around the patient's upper arm in the manner previously described.

Step 2

With your nondominant hand, palpate the patient's radial pulse on the same arm as the cuff. After you have located it, do not move your fingertips until you have completed taking the blood pressure.

Step 3

While holding the ball-pump in your other hand, close the turn-valve and slowly inflate the cuff until the pulse disappears and then continue to inflate another 30 mm Hg. As the cuff inflates, you will no longer feel the pulse under your fingertips.

Step 4

Open the turn-valve so that air slowly escapes from the cuff, and carefully observe the gauge. When you can again feel the radial pulse under your fingertips, note the reading on the gauge as the patient's systolic blood pressure.

Step 5

Next, open the turn-valve further, and completely deflate the cuff. Document your findings, including the time, and note that the pressure was taken by palpation.

Typically, you will assess fewer children than adults; therefore, you might not remember the normal ranges for the various age groups. It is a good idea to carry a chart with you that lists normal blood pressure ranges and other vital signs.

Words of Wisdom

Often, the most important information associated with the blood pressure is not the absolute value at any one point, but the trend in the pressure over the course of time you are caring for a patient.

When assessing a patient's general circulation, the blood pressure, pulse, skin temperature, and capillary refill should not be assessed in an injured limb. However, after you have obtained these vital signs from an uninjured limb, you might want to compare the distal skin temperature, quality of the distal pulse, and/or CRT in the injured limb with those found on the uninjured side. This information is useful in evaluating whether the injury may have compromised the circulation in the injured limb.

Neurologic System

A neurologic assessment should be performed any time you are confronted with a patient who has changes in mental status, a possible head injury, stupor, dizziness, drowsiness, or syncope. A neurologic assessment begins without even touching the patient. It can be as simple as talking with the patient, asking questions, and evaluating the reply from the patient. This step may be performed during the primary survey.

Evaluate the LOC and orientation to determine the patient's ability to think. Use the AVPU scale to determine the patient's mental status. Is the person alert and oriented to person, place, time, and event? Is the patient responsive or unresponsive? Does the patient respond to verbal or painful stimuli? If the patient is responsive, then evaluate speech for clarity, speed, organization, and logic. When evaluating speech, look for evidence of unusual reasoning or delusional thoughts. Consider the following questions to help assess the neurologic system:

- What is the patient's activity level?
- What are the patient's mood and thought content?

- What do the patient's facial expressions tell you? Is the patient angry, fearful, depressed, anxious, or restless?
- Does the patient appear uncomfortable?
- Does the patient make incomprehensible or understandable statements?
- Is the patient's memory affected?
- Does the patient remember who family members are?
- What is the patient's perception or view of what is happening?

Inspect the head for trauma. Pulse, blood pressure, and skin changes may indicate hypoperfusion of the brain.

You can further assess mental status by considering whether the patient is alert and oriented (A × O) in four areas: person, place, time, and the event itself, and determining the GCS score, as discussed in the Primary Survey section of this chapter.

Finally, as part of your brief neurologic evaluation, assess for any gross neurologic deficits by having the patient carefully move all extremities to pinpoint any motor deficits. Assess bilaterally for motor strength or weakness by asking the patient to move each extremity against the resistance of your hands. Assess grip strength by having the patient squeeze two of your fingers bilaterally and simultaneously, so that any unilateral neurologic deficits will be obvious. Quickly assess for any loss of sensation by touching the distal portions of the extremities with a blunt or sharp object to assess for any gross sensory defects.

Pupils

Assessing the pupils is an important consideration when assessing the neurologic system (**TABLE 10-7**). The pupil is the black center of the pigmented iris of the eye. The diameter and reactivity to light of the patient's pupils reflect the status of the brain's perfusion, oxygenation, and condition. The pupils are normally round and of approximately equal size and adjust in size depending on the available light. Normally, pupil size changes instantly to any change in light level. In normal room light, the pupil should appear to be midsize. When a bright light is suddenly introduced, the pupils instantly constrict, allowing less light to enter, protecting the sensitive receptors in the inner eye from damage (**FIGURE 10-35A**). When a bright light is introduced

TABLE 10-7 Pupillary Reactions

Appearance	Possible Causes
Round and equal size	Normal condition
Fixed with no reaction to light	Depressed brain function (head injury or stroke)
Fully dilated and fixed (blown pupil)	Increased intracranial pressure
Dilate with bright light, constrict with low light	Depressed brain function
Constricted	Drugs (opiates) or bright light
Dilated	Drugs (barbiturates) or dim lighting
Sluggish reaction	Severe increase in intracranial pressure
Unequal size	Depressed brain function Medication placed in eye Injury or condition of the eye Congenital anisocoria (normally unequal pupils) ^a

^a Approximately 20% of the population has anisocoria. In such cases, the pupils usually differ in size by less than 1 mm. (Anisocoria and Horner's syndrome. American Association for Pediatric Ophthalmology and Strabismus website. <https://aapos.org/glossary/anisocoria-and-horners-syndrome>. Updated March 2020. Accessed July 13, 2020.)

© Jones & Bartlett Learning.

into one eye (or higher levels of light enter one eye only), both pupils should constrict equally to the appropriate size for the pupil receiving the most light.

With less light, the pupils dilate, allowing more light to enter the eye, making it possible to see even in dim light. In the absence of any light, the pupils will become fully relaxed and dilated (**FIGURE 10-35B**). When light is introduced, each eye sends sensory signals to the brain, indicating the level of light it is receiving. Pupil size is regulated by a series of continuous motor commands that the brain automatically sends through the oculomotor nerves (third cranial nerve) to each eye, causing both pupils to constrict to the same appropriate size. In the presence of light, a single pupil that remains fully dilated is generally caused by pressure

**A****B****C**

FIGURE 10-35 A. Constricted pupils. B. Dilated pupils. C. Unequal pupils (anisocoria).

© American Academy of Orthopaedic Surgeons.

on the oculomotor nerve on that side of the head due to increasing intracranial pressure. Bilateral dilated pupils that do not respond to light are usually due to death.

A small number of people have normally unequal pupils (anisocoria), which is usually congenital (**FIGURE 10-35C**). If the patient or family member cannot confirm the presence of this condition, then you must assume the patient has depressed brain function as a result of CNS depression or injury if the pupils react in any of the following ways:

- Become fixed (either dilated or constricted) with no reaction to changes in light

- Dilate with introduction of a bright light and constrict when the light is removed
- React sluggishly instead of briskly
- Become unequal in size
- Become unequal in size when a bright light is introduced into or removed from one eye

Some of the causes of depressed brain function include the following situations:

- Injury of the brain or brainstem
- Trauma
- Stroke
- Brain tumor
- Inadequate oxygenation or perfusion
- Drugs or toxins (CNS depressants)

Words of Wisdom

Opiates, which are one category of CNS depressants, cause the pupils to constrict significantly, regardless of light. They become so small as to be described as pinpoint. Intracranial pressure from intracranial bleeding may cause sufficient pressure against the oculomotor nerve on one side so that the motor commands can no longer pass from the brain to that eye. When this occurs, the eye no longer receives commands to constrict, and its pupil becomes fully dilated and fixed. This finding is described as a “blown” pupil.

The mnemonic PERRLA is a useful guide in assessing the pupils. The letters stand for the following:

- P** Pupils
- E** Equal
- R** Round and
- R** Reactive to
- L** Light and
- A** Accommodation

For patients with normal pupils, medical care providers often report that “pupils are equal, round, and reactive to light and accommodation (react properly)” or “PERRLA.” Describe any abnormal findings using the longer form, such as “Pupils are equal and round, the left pupil is fixed and dilated, and the right pupil is regular in size and reacts to light.” Accommodation refers to the change in pupillary diameter that occurs when the patient changes focus from objects that are near to objects that are far away. When focusing on objects that are

nearby, the pupils normally constrict. When focusing on objects at a distance, pupils typically expand. Because accommodation is rarely tested in the pre-hospital environment, EMS agencies generally report the normal result of a pupillary exam as PERRL.

Assessing Neurovascular Status

Now perform a hands-on assessment to determine motor and sensory response. How does the patient move? Check for bilateral muscle strength and weaknesses. Complete a thorough sensory assessment. Test for pain, sensations, and position, and compare distal and proximal motor and sensory responses and one side with the other. Remember that a physical exam to address a specific chief complaint can be streamlined to assess a specific area of concern.

Anatomic Regions

Head, Neck, and Cervical Spine

Inspect for abnormalities of the head, neck, and cervical spine. Gently palpate the scalp and skull for any pain, deformity, tenderness, **crepitus**, and bleeding (**FIGURE 10-36**). Ask responsive patients if they feel any pain or tenderness. Look at the patient’s face. Is it symmetric? Is any evidence of trauma present, such as ecchymosis or hematomas? Does the patient have any facial expressions such as a smile or grimace? Check the patient’s face for the presence of a rash and petechiae (tiny red,

FIGURE 10-36 Gently palpate the head for any pain, deformity, tenderness, crepitus, and bleeding.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

purple, or brown spots on the skin caused by bleeding that may look like a rash), which suggest an infectious process and should alert you to the necessity for a mask and goggles. Check the patient's eyes, and assess pupillary function, shape, and response. Are the pupils equal in size and reactive to light, or are they constricted, dilated, or unequal? Check the color of the sclera. Check for foreign objects or blood in the eye and for bruising or discoloration around the eyes and behind the ears; these signs may be associated with head trauma. Assess the patient's zygomas for possible injury. Check the patient's ears and nose for fluid. Next, before opening the patient's mouth, check the upper (maxilla) and lower (mandible) jaws. After the patient's jaws have been assessed and it has been determined that movement will not create additional pain or injury, open the patient's mouth, looking for any broken or missing teeth. Blood and secretions impairing the airway should have been corrected during the primary survey. Before moving on to the neck, note any unusual odors that may be present in the patient's mouth. Odors such as a strong alcohol odor or fruity odor suggest the need to check the blood glucose level.

Words of Wisdom

Because many steps require patient cooperation, you will not be able to assess motor and sensory function in an unresponsive patient. A Babinski test may be used to check for sensation in an unresponsive patient. This test is accomplished by rubbing a pen or other object along the sole of the patient's foot. A normal reaction in young children and infants is for the great toe to flex toward the top of the foot and the other toes to fan out. However, this is an abnormal reaction in older children and adults. Do not perform a Babinski test on a patient who has injuries to the lower extremities. This test could cause the patient to pull the leg back, causing further injury.

Next, check the neck for signs of swelling or bleeding. Palpate the neck for signs of trauma, such as deformities, bumps, swelling, bruising, and bleeding, and for a crackling sound produced by air bubbles under the skin, also known as **subcutaneous emphysema** (FIGURE 10-37). Also, in patients in whom spinal injury is not suspected, inspect for pronounced or distended jugular veins

FIGURE 10-37 Gently palpate the neck.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

with the patient sitting at a 45° angle. This is a normal finding in a person who is lying down; however, jugular venous distention in a patient who is sitting up suggests a problem with blood returning to the heart. Carefully report and record your findings.

Chest

Next, expose the patient's chest. Inspect, visualize, and palpate over the chest area for injury or signs of trauma, including bruising, tenderness, and swelling. Watch the chest rise and fall with breathing. Normal breathing should be symmetric, in which both sides of the chest rise and fall together. Look for signs of abnormal breathing, including retractions (when the skin pulls in around the ribs during inspiration) and **paradoxical motion** (when one section rises on inspiration while the remainder of the chest falls).

Intercostal retractions indicate that the patient has some condition that is impairing the flow of air into and out of the lungs. Paradoxical motion is associated with a fracture of several ribs, with each rib fractured at more than one location (flail chest), causing a section of the chest to move independently from the rest of the chest wall. When palpating the chest, note if there is any crepitus, which is indicative of fractured ribs. Do not purposely elicit for crepitus because this action may cause further injury to the patient. Palpate the chest for subcutaneous emphysema, especially in cases of severe blunt chest trauma. This finding could indicate a pneumothorax.

Auscultate breath sounds as described previously. Evaluate air movement in and out of the lungs and to determine the presence of unilaterally diminished or absent breath sounds. You may hear normal breath sounds or adventitious breath sounds (crackles, wheezes, rhonchi, stridor, or pleural friction rub). Remember that breath sounds are easier to hear from the patient's back; place the stethoscope under the patient's clothing, and be sure to compare side to side, listening over the upper part of the lungs (apices), the lower part of the lungs (bases), and the major airways (midclavicular and midaxillary lines). If the patient's breathing is abnormal, then reassess breathing and, if appropriate, assist with ventilations.

Abdomen

Look for trauma to the abdomen and for distention. Palpate the abdomen for tenderness, rigidity, and patient **guarding**. If the patient is alert, then ask about pain as you perform the exam. Expose the site, and visually inspect the abdomen for bruising or other discoloration, bleeding, swelling, masses, and/or a pulsating mass (pulsations of the aorta caused by an abdominal aortic aneurysm). Bruising over the flank area suggests blood collecting in the retroperitoneal space and may occur from trauma or from a ruptured or "leaking" organ such as the aorta or a kidney. Asymmetry may suggest a swollen organ immediately under that area. The most frequently noted asymmetry is the result of an inflamed liver in patients with cirrhosis or hepatitis. Gentle pressure in that area often results in jugular venous distention. Distention may not be readily apparent. Also note changes if the patient is pregnant.

How rapidly the distention has occurred is important for the receiving hospital to know. Severe distention may be caused by fluid in the peritoneal space, as in **ascites**; blood, as in a slow leak from a rupture; obstruction, as in a bowel blockage; or infection, as in some cases of **sepsis**. Reassess frequently to determine if distention is increasing.

Be sure to palpate the abdomen, evaluating for symmetry, masses, tenderness, and bleeding (**FIGURE 10-38**). As you palpate the abdomen, use the terms *firm*, *soft*, *tender*, or *distended* (swollen) to report your findings. The abdomen is divided into four quadrants: left upper quadrant (LUQ), left

FIGURE 10-38 Palpate the abdomen, evaluating for symmetry, masses, tenderness, and bleeding.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

lower quadrant (LLQ), right upper quadrant (RUQ), and right lower quadrant (RLQ). Always start the palpation of the abdomen in the quadrant that is farthest from the patient's pain or obvious injury. Do not palpate obvious soft-tissue injuries, and be careful not to palpate too firmly.

Assess for the presence of **rebound tenderness**. Rebound tenderness is pain that the patient feels when pressure is released as opposed to when pressure is applied and is characteristic of peritonitis, which occurs with appendicitis. Assessing for rebound tenderness can be done by applying gentle, steady pressure on the abdomen and then releasing quickly. Explain to the patient ahead of time what you intend to do so that you gain valuable information. For example, tell the patient, "I am going to press on your abdomen and hold it for a couple of seconds and then let go. I need you to tell me if the pain is worse when I press down or when I let go." The same assessment can be accomplished by

Words of Wisdom

Assess the abdomen for the following:

- Tenderness
- Rigidity
- Swelling
- Guarding
- Distention
- Rebound tenderness

determining whether abdominal pain is produced by having the patient cough or tapping the heel of the patient's foot on the affected side. Note the position in which the patient is most comfortable.

Pelvis

Inspect the pelvis for symmetry, instability, pain, tenderness, crepitus, bleeding, deformity, and any obvious signs of injury; all findings may indicate a fractured pelvis and the potential for severe internal hemorrhage and shock. If the patient reports no pain, then gently press downward and inward on the iliac crests of the pelvic bones (**FIGURE 10-39**). Do not rock the pelvis; this action may result in torquing the spine and creating further injury. If you feel any movement or crepitus or the patient reports pain or tenderness, then severe injury may be present. Injuries to the pelvis and surrounding abdomen may bleed profusely without any obvious external signs, so continue to monitor the patient's mental status, skin condition, and vital signs. Provide supplemental oxygen as needed to minimize the effects of shock.

Inspection of the pelvic area, including the genitalia, is not often done in patients with medical emergencies, except when pain and bleeding is present. In female patients, it is ultimately important to determine whether the bleeding is coming from the vaginal opening, the urethra, female external genitalia, or the rectum. In male patients, it is ultimately essential to determine whether bleeding

is coming from the urethra or the rectum. In general, however, reporting on the presence of bleeding from the pelvic region is sufficient information from a prehospital care perspective. This information is extremely important in treating the patient after arrival at the hospital but will not change the AEMT's care of the patient.

Extremities

An assessment of the patient's musculoskeletal system typically is done because of a chief complaint associated with some type of trauma or due to the MOI. Do all extremities appear to be properly positioned, and do all extremities appear to be functioning normally? Assess for posture if standing, and look at joints, checking for range of motion. Ask patients how much they can move their extremities or joints. Never force a painful joint to move. Always compare the right side with the left side, looking for weakness or atrophy, and assess equality of grip strength.

Inspect each extremity for DCAP-BTLS (**FIGURE 10-40**). Ask the patient about any tenderness or pain. As you evaluate the extremities, check for pulses, motor function, and sensory function:

- **Pulse.** Check the distal pulses on the wrist (the radial pulse) and the foot (the dorsalis pedis pulse [**FIGURE 10-41**] or the posterior tibial pulse [**FIGURE 10-42**]). Assess the pulses in the lower extremities for rate, quality, and rhythm.

FIGURE 10-39 Inspect the pelvis for any obvious signs of injury, bleeding, and deformity.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

FIGURE 10-40 Inspect each extremity for DCAP-BTLS (Deformities, Contusions, Abrasions, Punctures/penetrations, Burns, Tenderness, Lacerations, Swelling).

© Jones & Bartlett Learning. Courtesy of MIEMSS.

FIGURE 10-41 Palpation of the dorsalis pedis pulse.

© Jones & Bartlett Learning.

FIGURE 10-42 Palpation of the posterior tibial pulse.

© Jones & Bartlett Learning.

Is the pulse fast, slow, or irregular? Is the pulse weak, thready, or bounding? Compare pulses with one another (compare radial, femoral, and pedal pulses). A difference from one side to the other suggests unilateral impairment of arterial blood flow. Also check circulation. Evaluate the skin color and temperature in the hands and feet. Is it normal? How does it compare with the skin color and temperature of the other extremities? Pale or cyanotic skin may indicate poor circulation in that extremity.

- **Motor function.** Ask patients to wiggle their fingers and toes. An inability to move a single extremity can be the result of a bone, muscle, or nerve injury. An inability to move several extremities may be a sign of a brain abnormality or spinal cord injury. Assess grip strength to determine ability and equality by having patients

squeeze your fingers. Ensure you are maintaining spinal motion restriction if indicated.

- **Sensory function.** Evaluate sensory function in the extremity by asking patients to close their eyes. Gently squeeze or pinch a finger or toe, and ask patients to identify what you are doing. The inability to feel sensation in an extremity may indicate a local nerve injury. The inability to feel in several extremities may be a sign of a spinal cord injury. Ensure you are maintaining spinal motion restriction, if indicated.

Palpate each extremity individually. Note the temperature of the feet and legs, and attempt to palpate edema in the legs. To do so, press your thumb over the dorsum of the foot and anteriorly over the tibia, holding the thumb with firm, gentle pressure for at least 5 seconds. Pitting edema occurs when depression of the skin causes an indentation that persists for some time after the pressure is released. Bilateral pitting edema is indicative of conditions such as right-side heart failure, whereas unilateral edema occurs with local conditions such as occlusion of a deep vein.

Pay close attention to the color of the hands and arms in comparison with one another. A ruddy color in one arm suggests obstruction of venous return, whereas edema suggests blockage of the lymphatic system.

Assessment of the hands and feet, particularly the nail beds, can give you clues to adequacy of perfusion and oxygenation. Note the color of the fingers and nail beds. Cyanosis may be noted; an early onset of cyanosis may cause the nail beds to darken and appear gray.

Posterior Body

Inspect the back for DCAP-BTLS, symmetry, bleeding, and open wounds (**FIGURE 10-43**). When placing the patient onto a backboard, it is particularly important that you check the back as you log roll the patient. Ensure you keep the spine in line at all times as you log roll the patient. Do not remove the hand that is supporting the shoulder because this could cause the spine to torque and create further injury. Carefully palpate the spine from the neck to the pelvis with the other hand, examining for tenderness or deformity, and look for obvious injuries, including bruising and bleeding. In addition, assess for the presence of rectal bleeding.

FIGURE 10-43 Feel the back for tenderness, deformity, and open wounds. Carefully palpate the spine from the neck to the pelvis for tenderness and deformity. Look under the clothing for obvious injuries, including bruising and bleeding.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Words of Wisdom

Pitting edema is graded on a scale of 1 to 4, based on the depth of the indentation that occurs when the skin is depressed.

- +1 = 0 to 0.25 inch (<6.5 mm)
- +2 = 0.25 to 0.5 inch (6.5 to 12.5 mm)
- +3 = 0.5 to 1 inch (12.5 to 2.5 cm)
- +4 = >1 inch (>2.5 cm)

Additional Physical Exams

After you have performed the secondary assessment, if time permits during transport, you may decide to perform a focused assessment of each body system (including areas that you did not initially assess). In many cases, you will not have time for

this detailed exam, but when time permits, you may learn additional information about the patient's complaint by performing this exam.

When you have time to perform a focused assessment of each body system, begin by asking yourself two questions: "What additional problems can be identified through this exam?" and "How will these findings change my treatment choices?" These exams will provide you with additional information that will enable you to recognize patterns of response, particularly compensatory mechanisms, and help you understand more about the nature of the patient's problem. Actions you may need to take as a result of findings include the following:

- Addressing any potentially life-threatening conditions (this is unlikely this late in the exam but is possible). Certain conditions, such as a pneumothorax or bleeding in the peritoneal cavity, may not be readily apparent during your initial assessment, but may be obvious at this point.
- Establishing spinal motion restriction if neck or back pain or abnormality in sensation or movement is identified in relationship to trauma (This is unlikely but could occur, especially in the case of a spinal cord contusion in a pediatric or geriatric patient.)
- Modifying any treatment that is underway on the basis of any new information
- Initiating treatment for additional problems identified during the focused exams
- Modifying transport decisions to a more appropriate facility, if the patient's condition deteriorates or potential life threats develop

Patient Assessment

Reassessment

A **reassessment** is performed at regular intervals during the assessment process, and its purpose is to identify and treat changes in a patient's condition. When you perform reassessment, reassess the ABCDEs to ensure you adequately addressed the chief complaint, obtained another set of vital signs, and completed any other tasks related to patient care (such as dressing small wounds or placing ice packs). Reassessment represents a continuous, cyclical process you perform throughout transport, right up to the time you turn over patient care to the ED staff. For patients in stable condition, do a

reassessment every 15 minutes or so. For patients in unstable condition, make a concerted effort to repeat the reassessment every 5 minutes.

Words of Wisdom

Reassess stable patients every 15 minutes and unstable patients every 5 minutes.

Repeat the Primary Survey

Reassessment combines repetition of the primary survey, reassessment of vital signs and breath sounds, and repetition of the secondary assessment.

First, compare the patient's LOC with your baseline assessment. Is the LOC changing? If so, then how?

Reassess Vital Signs

Reassess and record the vital signs. Compare the baseline vital signs obtained during the primary survey with any and all subsequent vital signs. Look for trends. Have the vital signs changed, improved, declined, or stayed the same? Reassess the mental status and the ABCs. Monitor skin color and temperature. Reassess the blood pressure and pulse.

Reassess the Chief Complaint

Reassess the patient's chief complaint in the light of treatments provided thus far. Ask and answer the following questions about the patient's chief complaint:

- Is the current treatment improving the patient's condition?
- Has an already identified problem gotten better?
- Has an already identified problem gotten worse?
- What is the nature of any newly identified problems?

Recheck Interventions

In the reassessment process, reevaluate everything that has been done to this point in the patient

assessment process. Check all interventions. Management of the patient's ABCs is most important. In addition, are the bandages, spinal motion restriction devices, extrication equipment, and patient-securing instruments in place and appropriate for transport? Are IV lines flowing properly, or does the rate need to be changed based on patient presentation or changes in patient condition? Ensure management and control of bleeding. Ensure adequacy of other interventions, and consider the need for new interventions.

Identify and Treat Changes in the Patient's Condition

No matter what the patient's condition was before your arrival, which interventions were used, or which decisions on treatment and transport priorities were made, a reassessment is necessary to help monitor changes in the patient's condition. If the patient's condition improves, then simply continue whatever treatments you are providing. If the patient's condition deteriorates, then prepare to modify treatments as appropriate. Document any changes, whether negative or positive.

Reassess the Patient

How and when to perform a reassessment depends on the patient's condition. A patient in unstable condition should be reassessed every 5 minutes, whereas a patient in stable condition should be reassessed every 15 minutes.

YOU are the Provider SUMMARY**1. What are the components of a scene size-up?**

The components of a scene size-up include information that you receive from your dispatcher and other agencies already on scene, combined with a visual inspection of the scene in an attempt to identify any potential safety hazards to your crew, the patient, and bystanders. Another component is confirming the number of patients to ensure you have adequate resources to care for the patients.

2. What can you do to ensure scene safety?

You must recognize that hazards come in many different forms, shapes, and sizes. Initial information obtained by your dispatcher can alert you to possible scene hazards. Hazards exist at every MVC scene. Strategically position your emergency vehicle in a manner that will minimize risk to responders. Also, fluids leaking from a wrecked vehicle can be extremely slippery when they come in contact with a road surface. Look for possible dangers as you approach the scene and before you step out of the vehicle. Observe unstable surfaces, slopes, ice, water, and wet grass. Consider the location of your patient and the conditions. You are obliged to provide protection for the patient.

Occasionally, you and your partner will not be able to enter a scene safely. If the scene is unsafe, then make it safe. If this is not possible, then do not enter. If the hazard presents a substantial risk to your health and safety, then request the appropriate assistance. If the scene is a potential crime scene, then follow local protocols before entering. Ask for law enforcement personnel to accompany you when needed.

3. Does this patient present more like a medical patient or a trauma patient?

One of the great dangers in performing the prehospital assessment is categorizing your patient immediately as either a trauma (injured) patient or a medical (ill) patient. Early in the assessment, it can be difficult to identify with absolute certainty whether the problem is of traumatic or medical origin. Consider the patient in this scenario. Did she strike the tree and become unresponsive? Or did she experience a medical problem that caused her to strike the tree? Remember, the fundamentals of good patient assessment do not change, despite the unique aspects of trauma and medical care.

4. What type of PPE should you wear for this type of call?

Standard precautions and PPE need to be considered and adapted to the prehospital task at hand. Included in PPE is the clothing or specialized equipment that provides protection to the wearer. The type of PPE required depends on the specific job duties required during a patient care interaction and the presence or absence of community transmission of aerosolized pathogens. For an MVC, gloves are usually sufficient for those providing patient care. If there is risk for blood splatter, a gown and goggles should be worn in addition to gloves. These measures may not provide absolute protection from exposure to infectious diseases or bloodborne pathogens, but they are the most effective way to reduce your risk of exposure.

5. What are the components of the GCS score?

The GCS uses parameters that test a patient's eye opening, best verbal response, and best motor response, which provide a numeric score that defines the severity of a patient's brain dysfunction. This information provides baseline data on the patient's overall neurologic status and can be a reliable predictor of the outcome of a patient with a brain injury. When you are reporting the GCS score, document or report each section (eg, Eye opening, 3; Verbal response, 2; Motor response, 4; GCS score, 9) to document baseline function in each area.

6. How can you rule in or rule out diabetes as the cause of her altered mental status?

The glucometer is used to assess blood glucose levels, which can assist you in determining if the glucose level is the cause of the patient's altered mental status. Although determining glucose levels is largely a routine part of the patient assessment, indications include known diabetes in patients with a decreased LOC, a decreased LOC of unknown origin in any patient, general malaise, weakness, or a poor general impression. A normal glucose reading is 80 to 120 mg/dL.

7. How often should you reassess your patients?

Reassess patients in critical or unstable condition every 5 minutes and patients in stable or noncritical condition every 15 minutes. Performing reassessments at these intervals provides a method for you to recognize any improvement or deterioration in the patient's status.

YOU are the Provider SUMMARY *continued***8. Why is critical thinking important as an AEMT?**

The prehospital setting may be one of controlled chaos; your sources of information can be overwhelming or severely limited. You must be able to prioritize this information in a short time, separate relevant from irrelevant data, and provide the most appropriate care for the patient. These abilities are the cornerstones of being an effective EMS provider.

Gathering, analyzing, and correctly synthesizing patient information will culminate in an appropriate treatment plan. This process requires an understanding of the patient's injury or illness and the effect that your emergency medical care will have on it. You will develop needed critical thinking skills through field experience in dealing with multiple patients with varying problems.

Prehospital Treatment (circle all that apply)

Oxygen @ <u>15</u> L/min via (circle one): NC (NRM) Bag-mask device		Assisted Ventilation	Airway Adjunct	CPR
Defibrillation	Bleeding Control	Bandaging	Splinting	Other: Spinal motion restriction established; IV line established

Narrative

EMS requested to an MVC involving vehicle vs. tree. On arrival, EMS finds an adult female patient sitting in driver's seat with lap and shoulder belt still in place. There is severe damage to the front of the vehicle and the windshield is cracked in multiple places. Access is gained by opening the driver's door and manual spinal motion restriction established. The patient is alert but confused, and she reports neck pain. Respirations are adequate, breath sounds are clear and equal bilaterally, radial pulses are strong and regular, and skin is warm and dry. Blood glucose level is 98 mg/dL. Patient presents with a large hematoma on her forehead and her pupils are equal and reactive to light. She has good pulses, motor function, and sensation in all extremities, but reports a "tingling" sensation. Patient is placed on O₂ via NRB mask at 15 L/min. A cervical collar is applied and the patient is removed from the vehicle onto a long backboard using a vest-style extrication device. She is secured to the backboard and placed in the ambulance for transport. En route to the trauma center, patient is reassessed with no changes found and an 18-gauge IV line is established with NS at a TKO rate. Patient left in care of ED staff for further evaluation.

End of report

Prep Kit

Ready for Review

- Critical thinking includes gathering, evaluating, and synthesizing patient information, developing an idea of the patient's problem based on gathered information and the patient's presentation, and formulating a field impression on which an appropriate patient treatment plan will be based. Learn and practice the key elements of critical thinking so you can apply them when in the field.
- Always base your treatment or transport decisions on your assessment of the patient.
- The assessment process begins with the scene size-up, which identifies real and potential hazards. The patient should not be approached until these hazards have been dealt with in a way that eliminates or minimizes risk to you and the patient or patients.
- The primary survey is performed on all patients. It includes forming an initial general impression of the patient, including the LOC, and identifying any life-threatening conditions by assessing the XABCDEs. A primary survey is performed to assist in prioritizing time and mode of transport. Any life threats identified must be treated before moving on to the next step of the assessment.
- History taking includes an exploration of the patient's chief complaint or history of present illness. A SAMPLE history is generally taken during this step of the assessment process. This information may be obtained from the patient, family, friends, bystanders, caregivers, or medical alert devices or documentation.
- The secondary assessment includes physical exam of the patient. The physical exam may be a systematic full-body exam or a systematic assessment that focuses on a certain area or region of the body, often determined through the chief complaint. Circumstances will dictate which aspects of the physical exam will be used. The secondary assessment is performed on scene or in the back of the ambulance en route to the hospital. If the patient has serious life threats, then you may not have time to perform a secondary assessment.
- The reassessment is performed on all patients. It gives you an opportunity to reevaluate the chief complaint and to reassess interventions to ensure they are still effective. Information from the reassessment may be used to identify and treat changes in the patient's condition.
- A patient in stable condition should be reassessed every 15 minutes, whereas a patient in unstable condition should be reassessed every 5 minutes.
- The assessment process is systematic and dynamic. Each assessment you perform will be slightly different, depending on the needs of the patient. The result will be a process that will enable you to quickly identify and treat the needs of all patients, both medical and trauma related, in a way that meets their unique needs.

Vital Vocabulary

accessory muscles The secondary muscles of respiration that include the neck muscles (sternocleidomastoids), the chest's pectoralis major muscles, and the abdominal muscles.

adventitious sounds Abnormal breath sounds that include crackles, rhonchi, wheezes, stridor, and pleural friction rubs.

altered mental status Any deviation from alert and oriented to person, place, time, and event,

or any deviation from a patient's normal baseline mental status; may signal disease in the central nervous system or other contributing factors.

anisocoria Uneven pupil size; can be naturally occurring, but also can be a sign of pathology.

ascites The accumulation of serous fluid in the peritoneal cavity, typically signaling liver failure.

aspiration The inhalation of liquid or solid matter into the lungs through the trachea, typically

as a result of an incompetent gag reflex or over-aggressive resuscitation technique; may occur when the patient is unable to maintain the airway and blood or fluid is present in the mouth.

auscultation A method of listening to sounds within an organ with a stethoscope.

AVPU scale A mnemonic to describe the method of assessing the level of consciousness by determining whether the patient is Awake and alert, responsive to Verbal stimuli or Pain, or Unresponsive; used principally early in the assessment process.

blood pressure The pressure that the blood exerts against the walls of the arteries as it passes through them.

bradycardia A slow heart rate; less than 60 beats/min in adults; less than 80 beats/min in children; and less than 100 beats/min in infants.

breath sounds An indication of air movement in the lungs, usually assessed with a stethoscope.

bronchovesicular sounds Soft, breezy, and low-pitched normal breath sounds found at the mid-clavicular line.

capillary refill A test that evaluates distal circulatory system function by squeezing (blanching) blood from an area such as a nail bed and watching the speed of its return after releasing the pressure.

capnography A noninvasive method that can quickly and efficiently provide information on a patient's ventilatory status, circulation, and metabolism; effectively measures the concentration of carbon dioxide in expired air over time.

capnometry The use of a capnometer, a device that measures the amount of expired carbon dioxide.

carbon dioxide (CO₂) A component that typically makes up 0.3% of air at sea level; also a waste product exhaled during expiration by the respiratory system.

chief complaint The reason a patient called for emergency medical services; also, the patient's response to questions such as "What's wrong?" or "What happened?"

colorimetric devices End-tidal carbon dioxide detectors that use a chemical reaction to detect the amount of carbon dioxide present in expired gases.

conjunctiva The delicate membrane that lines the eyelids and covers the anterior exposed surface of the eye.

crackles Crackling, moist breath sounds signaling fluid in the smaller air passages of the lungs; formerly called rales.

crepitus A grating or grinding sensation caused by fractured bone ends or joints rubbing together; also, air bubbles under the skin that produce a crackling sound or crinkly feeling.

cyanosis A blue-gray skin color that is caused by a reduced level of oxygen in the blood.

DCAP-BTLS A mnemonic for assessment in which each area of the body is evaluated for Deformities, Contusions, Abrasions, Punctures/penetrations, Burns, Tenderness, Lacerations, and Swelling.

diaphoretic Characterized by light or profuse sweating.

diastolic pressure The pressure that remains in the arteries during the relaxing phase of the cycle of the heart (diastole) when the left ventricle is at rest.

diffuse pain Pain that is not identified as being specific to a single location but is spread out over an area of the body or felt all over the body.

end-tidal carbon dioxide (ETCO₂) The partial pressure or maximal concentration of carbon dioxide at the end of an exhaled breath.

focal pain Pain that is easily identified as being specific to a single location of the body.

focused assessment A type of physical assessment typically performed on patients who have sustained nonsignificant mechanisms of injury or on responsive medical patients. This type of exam is based on the chief complaint and focuses on one body system or part.

full-body exam A systematic head-to-toe exam that is performed during the secondary assessment of a patient who has sustained a significant

mechanism of injury, is unresponsive, or is in critical condition.

general impression The overall initial impression that determines the priority for patient care; based on the patient's surroundings, the mechanism of injury, nature of illness, signs and symptoms, and the chief complaint.

Glasgow Coma Scale (GCS) A method of evaluating the level of consciousness that uses a scoring system for neurologic responses to specific stimuli.

Golden Hour The time from injury to definitive care, during which treatment of shock and traumatic injuries should occur because survival potential is best; sometimes called the Golden Period.

guarding Involuntary muscle contractions (spasm) of the abdominal wall to minimize the pain of abdominal movement and protect the inflamed abdomen; a sign of peritonitis.

history taking A step within the patient assessment process that provides detail about the patient's chief complaint and an account of the patient's signs and symptoms.

hypertension Blood pressure that is higher than the normal range.

hypotension Blood pressure that is lower than the normal range.

incident command system (ICS) An on-scene emergency management model specifically designed to provide for an integrated organizational structure that reflects the complexity and demands of an incident, including disasters and mass-casualty incidents. Also called the incident management system.

jaundice Yellow skin or sclera commonly caused by liver disease or dysfunction.

labored breathing Breathing that requires greater than normal effort; may be slower or faster than normal and characterized by grunting, stridor, and use of accessory muscles; occurs when air movement is impaired.

mechanism of injury (MOI) The forces, or energy transmission, applied to the body that cause injury; the way in which traumatic injuries occur.

medical ambiguity Uncertainty regarding the specific cause of the patient's condition.

mental model The overall picture that team members have in their head of what needs to happen to ensure an effective response.

mission-critical communications Any communications in which disruption will result in the failure of the task at hand.

nasal flaring Widening of the nostrils, indicating that an airway obstruction is present.

nature of illness (NOI) The general type of illness a patient is experiencing.

OPQRST A mnemonic used in evaluating a patient's pain: Onset, Provocation/palliation, Quality, Region/radiation, Severity, and Timing of pain.

orientation The mental status of a patient as measured by memory of person (name), place (current location), time (current year, month, and approximate date), and event (what happened).

palpate To examine by touch.

paradoxical motion The inward movement of the chest during inhalation and outward movement during exhalation; the opposite of normal chest wall movement during breathing; occurs in a flail chest.

perfusion The circulation of oxygenated blood within an organ or tissue in adequate amounts to meet the cells' current needs.

personal protective equipment (PPE) Equipment that blocks exposure to a pathogen or a hazardous material.

pertinent negatives Expected signs or symptoms with negative findings that warrant no care or intervention.

pleural friction rub A squeaking or grating sound that occurs when the pleural linings rub together, which may be heard on inspiration, expiration, or both; commonly caused by inflammation of the pleura.

priapism A painful, tender, and persistent erection of the penis; can result from spinal cord injury, use of erectile dysfunction drugs, or sickle cell disease.

primary survey A step within the patient assessment process that identifies and initiates treatment of immediate and potential life threats.

pulse The wave of pressure created as the heart contracts and forces blood out of the left ventricle and into the major arteries.

pulse oximetry An assessment tool that measures oxygen saturation of hemoglobin in the capillary beds.

radiating pain An area of the body from which the origin of pain or discomfort may travel.

rapid full-body scan A thorough, 60- to 90-second review of the patient's body to identify injuries that must be managed or protected immediately; conducted during the primary survey.

reassessment A step within the patient assessment process that is performed at regular intervals during the assessment process to identify and treat changes in a patient's condition. A patient in unstable condition should be reassessed every 5 minutes, whereas a patient in stable condition should be reassessed every 15 minutes.

rebound tenderness Pain that the patient feels when pressure is released as opposed to when pressure is applied; characteristic of appendicitis; suggestive of a serious and potentially life-threatening condition.

referred pain Pain in two separate locations of the body, without a "trail" of pain between the two locations, or pain in an area of the body that is not the source of the pain.

respiratory distress A clinical state characterized by increased respiratory rate, effort, and/or work of breathing.

respiratory failure A clinical state of inadequate oxygenation, ventilation, or both.

responsiveness The way in which a patient responds to external stimuli, including verbal stimuli (sound), tactile stimuli (touch), and painful stimuli.

retractions Movements in which the skin pulls in around the ribs during inspiration; the drawing in of the intercostal muscles and the muscles above the clavicles that can occur in respiratory distress.

rhonchi Coarse, low-pitched, rattling breath sounds heard in patients with chronic mucus in the upper airways.

SAMPLE history A brief history of a patient's condition to determine signs and symptoms, allergies, medications, pertinent past history, last oral intake, and events leading up to the illness or injury.

scene size-up A step within the patient assessment process that involves a quick assessment of the scene and the surroundings to provide information about scene safety and the mechanism of injury or nature of illness before you enter and begin patient care.

sclera The tough, fibrous, white portion of the eye that protects the more delicate inner structures.

secondary assessment A step within the patient assessment process in which a systematic physical exam of the patient is performed. The exam may be a full-body exam or an assessment that focuses on a certain area or region of the body, often determined through the chief complaint.

sepsis The spread of an infection from its initial site into the bloodstream.

shallow respirations Respirations characterized by little movement of the chest wall (reduced tidal volume) or poor chest excursion.

sign Objective finding that can be seen, heard, felt, smelled, or measured (eg, a laceration or the patient's blood pressure) when assessing a patient to establish illness or injury.

situational awareness Knowledge and understanding of one's surroundings and the ability to recognize potential risks to the safety of the patient or the emergency medical services team.

sniffing position A position in which the patient is sitting upright or lying on the back with the head and chin thrust slightly forward to keep the airway open; the optimum head position for the uninjured child who requires airway management.

spontaneous respirations Breathing that occurs without assistance.

standard precautions Protective measures that have traditionally been developed and

recommended by the Centers for Disease Control and Prevention for use in dealing with objects, blood, body fluids, and other potential exposure risks of communicable disease.

stridor A harsh, high-pitched breath sound, generally heard during inspiration, that is caused by partial blockage or narrowing of the upper airway; may be audible without a stethoscope.

subcutaneous emphysema A characteristic crackling sensation felt on palpation of the skin, caused by the presence of air in soft tissues.

symptom A subjective finding that the patient feels, but that can be identified only by the patient; for example, what the patient tells a provider during assessment.

systolic pressure The increased pressure in an artery with each contraction of the ventricles (systole).

tachycardia A rapid heart rate of more than 100 beats per minute.

tidal volume The amount of air (in milliliters) that is moved into or out of the lungs during one relaxed breath; approximately 500 mL for an adult.

triage The process of sorting patients based on the severity of injury and medical need to establish treatment and transportation priorities.

tripod position An upright position in which the patient leans forward onto two arms stretched forward and thrusts the head and chin forward.

two- to three-word dyspnea A severe breathing condition in which a patient can speak only two to three words at a time without pausing to take a breath.

vasoconstriction Narrowing of the diameter of a blood vessel.

vesicular sounds Fine and faint normal breath sounds noted in the lateral wall of the chest from the smaller bronchioles and alveoli.

vital signs Clinical measurements that indicate the current state of the body and how well it is functioning.

wheezing A high-pitched, whistling breath sound that is most prominent on expiration, and which suggests an obstruction or narrowing of the lower airways; occurs in asthma and bronchiolitis.

Airway

11 Airway Management

SECTION

4

Chapter 11

Airway Management

NATIONAL EMS EDUCATION STANDARD COMPETENCIES

Airway Management, Respiration, and Artificial Ventilation

Applies knowledge (fundamental depth, foundational breadth) of upper airway anatomy and physiology to patient assessment and management in order to assure a patent airway, adequate mechanical ventilation, and respiration for patients of all ages.

Airway Management

Airway anatomy (pp 542–546)

Airway assessment (pp 559–563)

Techniques of assuring a patent airway (p 550)

Respiration

Anatomy of the respiratory system (pp 542–546)

Physiology and pathophysiology of respiration

- Pulmonary ventilation (pp 548–551)

- Oxygenation (p 551)

- Respiration

- External (pp 551–552)

- Internal (pp 552–553)

- Cellular (p 551)

Assessment and management of adequate and inadequate respiration (pp 559–563)

Supplemental oxygen therapy (pp 580–586)

Artificial Ventilation

Assessment and management of adequate and inadequate ventilation

- Artificial ventilation (pp 589–598)

- Minute ventilation (p 555)

- Alveolar ventilation (p 555)

- Effect of artificial ventilation on cardiac output (p 590)

Pathophysiology

Applies comprehensive knowledge of the pathophysiology of respiration and perfusion to patient assessment and management.

KNOWLEDGE OBJECTIVES

1. Review the major structures of the respiratory system. (pp 542–546)
2. Discuss the physiology of breathing. (pp 546–548)
3. Describe factors related to ventilation, including partial pressure and volumes. (pp 548–550)
4. Describe factors related to the pathophysiology of respiration, including ventilation-perfusion ratio mismatch, hypoventilation, hyperventilation, and circulatory compromise. (pp 554–557)
5. Review the concept of acid-base imbalance. (pp 558–559)
6. Explain how to assess for adequate and inadequate respiration, including the use of pulse oximetry. (pp 563–565)
7. List the signs of adequate breathing. (p 559)
8. List the signs of inadequate breathing. (p 559)
9. Explain how to assess for a patent airway. (pp 559–560)

10. Describe abnormal breathing patterns to recognize when assessing a patient's breathing. (p 560)
11. Discuss the methods for end-tidal carbon dioxide assessment, including its importance. (pp 566–568)
12. Describe the assessment and care of a patient with apnea. (pp 561–562)
13. Describe how to perform the head tilt–chin lift maneuver. (pp 569–570)
14. Describe how to perform the jaw-thrust maneuver. (pp 570–571)
15. Explain the use of the recovery position to maintain a clear airway. (p 572)
16. Discuss the importance and techniques of suctioning. (p 574)
17. Explain the advanced emergency medical technician's (AEMT's) role in performing tracheobronchial suctioning. (pp 574–576)
18. Explain how to measure and insert an oropharyngeal (oral) airway. (pp 576–578)
19. Explain how to measure and insert a nasopharyngeal (nasal) airway. (pp 578–579)
20. Describe the importance of giving supplemental oxygen to patients who are hypoxic. (p 580)
21. Describe the basics of how oxygen is stored and the various hazards associated with its use. (pp 580–586)
22. Explain how to use a nonrebreathing mask, and state the oxygen flow requirements for its use. (pp 586–587)
23. Describe the indications for using a nasal cannula rather than a nonrebreathing face mask. (p 587)
24. Describe the indications for use of a humidifier during supplemental oxygen therapy. (pp 588–589)
25. Describe the use of a one-, two-, or three-person bag-mask device and a manually triggered ventilation (MTV) device. (pp 592–597)
26. Explain how to perform mouth-to-mouth or mouth-to-mask ventilation. (p 591)
27. Describe the signs associated with adequate and inadequate artificial ventilation. (p 596)
28. Describe the indications, contraindications, and complications of use of continuous positive airway pressure (CPAP). (pp 598–602)
29. Explain the considerations surrounding gastric distention. (p 602)
30. Discuss airway management considerations for patients with a laryngectomy, tracheostomy, or stoma. (pp 602–607)
31. Describe how to recognize and care for a foreign body airway obstruction. (pp 607–608)
32. Discuss supraglottic and multilumen airway devices, including how they work; their indications, contraindications, and complications; and the procedure for inserting them. (pp 608–611, 618–620)
33. Explain the role of the AEMT in assisting a paramedic partner with airway skills beyond the AEMT scope of practice. (pp 620–624)

SKILLS OBJECTIVES

1. Demonstrate use of pulse oximetry. (p 563)
2. Demonstrate how to position the unresponsive patient. (p 569, Skill Drill 11-1)
3. Demonstrate the steps in performing the head tilt–chin lift maneuver. (p 570)
4. Demonstrate the steps in performing the jaw-thrust maneuver. (p 571)
5. Demonstrate the steps in performing the tongue-jaw lift maneuver. (p 571)
6. Demonstrate how to place a patient in the recovery position. (p 572)
7. Demonstrate how to operate a suction unit. (p 573)
8. Demonstrate how to suction a patient's airway. (p 575, Skill Drill 11-2)
9. Demonstrate how to perform tracheobronchial suctioning. (p 576)
10. Demonstrate the insertion of an oral airway. (p 577, Skill Drill 11-3)
11. Demonstrate the insertion of an oral airway with a 90° rotation. (p 577, Skill Drill 11-4)
12. Demonstrate the insertion of a nasal airway. (p 579, Skill Drill 11-5)
13. Demonstrate how to place an oxygen cylinder into service. (pp 584–585, Skill Drill 11-6)
14. Demonstrate the use of a partial rebreathing mask in providing supplemental oxygen therapy to patients. (p 587)
15. Demonstrate the use of a Venturi mask in providing supplemental oxygen therapy to patients. (p 588)

16. Demonstrate the use of a humidifier in providing supplemental oxygen therapy to patients. (p 588)
17. Demonstrate how to assist a patient with ventilations using the bag-mask device for one and two rescuers. (p 596)
18. Demonstrate mouth-to-mask ventilation. (p 592, Skill Drill 11-7)
19. Demonstrate the use of an MTV device to assist in delivering artificial ventilation to the patient. (p 597)
20. Demonstrate the use of an automatic transport ventilator to assist in delivering artificial ventilation to the patient. (p 598)
21. Demonstrate the use of CPAP. (pp 600–601, Skill Drill 11-8)
22. Demonstrate how to suction a stoma. (p 603, Skill Drill 11-9)
23. Demonstrate mouth-to-stoma ventilation with a resuscitation mask. (p 605, Skill Drill 11-10)
24. Demonstrate bag-mask device-to-stoma ventilation. (p 606, Skill Drill 11-11)
25. Demonstrate insertion of the King LT airway. (pp 610–611, Skill Drill 11-12)
26. Demonstrate insertion of the laryngeal mask airway. (pp 613–614, Skill Drill 11-13)
27. Demonstrate insertion of an i-gel supraglottic airway. (pp 616–617, Skill Drill 11-14)
28. Demonstrate insertion of the Cobra perilaryngeal airway. (p 618)
29. Demonstrate insertion of the Combitube. (p 619)

Introduction

The single most important steps in caring for any patient are to obtain and maintain a patent airway and to ensure that the patient is breathing adequately. Within a few minutes of being deprived of oxygen, vital organs such as the heart and brain may not function normally. Brain cell death occurs within 4 to 6 minutes without oxygen.

Oxygen reaches body tissues and cells through two separate but related processes: breathing and circulation. During inhalation, oxygen moves from the atmosphere into our lungs and then passes from the alveoli in the lungs into the capillaries to oxygenate the blood. The blood, enriched with oxygen, travels through the body by the pumping action of the heart. At the same time, carbon dioxide, produced by cells in the body tissues, moves from the capillaries into the alveoli. The carbon dioxide then leaves the body during exhalation. The primary objective of emergency care is to ensure optimal ventilation—movement of air into and out of the lungs—to facilitate the delivery of oxygen and elimination of carbon dioxide.

Basic airway management skills tend to be taken for granted as more advanced skills are learned, yet they are among the most crucial skills any emergency medical services (EMS) provider learns. This chapter reviews the anatomy and physiology of the respiratory system. It then describes how to assess patients quickly and carefully to determine their

airway and ventilation status. The equipment, procedures, and guidelines that you will need to manage a patient's airway and breathing are described in detail. You will learn several ways to open a patient's airway and manage situations that place the airway in jeopardy. Because artificial airway equipment can cause harm to the patient if used improperly, the chapter will thoroughly discuss airway adjuncts, oxygen therapy devices, definitive airway equipment, and artificial ventilation methods.

Safety

A mask (preferably an N95 mask if there is active community transmission of respiratory viral disease), protective eyewear with side shields or goggles, and gloves should be worn whenever airway management involves suctioning. Body fluids can become aerosolized and can come in contact with the mucous membranes of your mouth, nose, and eyes, and your hands. For all airway procedures that potentially generate aerosolization (eg, assisted ventilation, airway insertion, suction) this level of PPE is necessary.

Anatomy Review

The respiratory system consists of all the structures in the body that make up the **airway** and help us breathe, or ventilate (**FIGURE 11-1**). The airway is divided into the upper and lower airways. Structures

FIGURE 11-1 The upper and lower airways contain the anatomic structures that help us breathe.

© Jones & Bartlett Learning.

that help us breathe include the diaphragm, the muscles of the chest wall, accessory muscles of breathing, and the nerves from the brain and spinal cord to those muscles. Ventilation is the exchange of air between the lungs and environment. The diaphragm and muscles of the chest wall are responsible for the regular rise and fall of the chest that accompany normal breathing.

The Upper Airway

The airway is divided into upper and lower airways. The larynx is considered the dividing line between the upper and lower airways.

The major functions of the upper airway are to warm, filter, and humidify air brought into the body. Air enters the body through the mouth and nose. Warming protects the patient from becoming hypothermic. Humidification is accomplished as the air picks up moisture from the tissues of the airway. The pharynx—the muscular tube that extends

from the nose and mouth to the level of the esophagus and trachea—is composed of the nasopharynx, oropharynx, and the laryngopharynx (also called the hypopharynx) (**FIGURE 11-2**). The laryngopharynx is the lowest portion of the pharynx. At the base, it splits into two lumens (a lumen is a channel within a tube), the larynx anteriorly and the esophagus posteriorly.

Nasopharynx

The union of the facial bones forms the nasopharynx. The nasopharynx is divided by the septum. The nasopharynx is lined with a ciliated mucosal membrane that keeps dust and small particles from entering the respiratory system. Cilia help move contaminants out of the body. During an illness, the body produces more mucus to trap potentially infectious agents.

From the lateral walls of the nose, three bony shelves called **turbinates** extend into the nasal

FIGURE 11-2 A. The oral cavity. **B.** The pharynx.

© Jones & Bartlett Learning.

passageway. They are parallel to the nasal floor. The turbinates serve to increase the surface area of the nasal mucosa, thereby improving filtration, warming, and humidification of inhaled air. The sinuses are cavities formed by the cranial bones. They further trap bacteria and viruses and act as tributaries for fluid to and from the eustachian tubes and tear ducts, and they commonly become infected. Because the cranial bones form the sinus cavities, fractures of certain sinus bones may cause a leakage of cerebrospinal fluid (CSF) into the nasal passageways and auditory canal.

The tissues of the nasopharynx are extremely delicate and highly vascular. Improper or overly aggressive placement of airway devices may cause substantial bleeding that cannot be controlled by direct pressure.

Oropharynx

The oral cavity begins with the mouth and teeth. The oral cavity is an alternate airway to the nose and is the entrance to the digestive system. The oropharynx is the part of the throat found at the posterior of the oral cavity. Recall from Chapter 7,

YOU are the Provider

Part 1

Your station is dispatched to a local assisted living center for a man in respiratory distress. As you call in, dispatch advises you that an ambulance is responding and is approximately 15 minutes away. As your engine arrives on scene, you are met by a frantic patient care attendant who states that the patient was just admitted to the facility earlier this morning, but now he does not seem to be breathing normally; however, she is unsure if this is normal for him or not. As you approach the patient's room, you ask if he is a full code, to which the patient care attendant replies "Yes."

1. How does the body regulate ventilation?
2. What are some of the factors that affect pulmonary ventilation?

The Human Body, that it contains the back third of the tongue, hyoid bone, soft palate, and the tonsils and adenoids.

The epiglottis is a leaf-shaped cartilaginous flap located at the base of the tongue and above the larynx at the superior border of the oropharynx that prevents food and liquid from entering the larynx during swallowing. When swallowing begins, laryngeal muscles contract to cause downward movement of the epiglottis and upward movement of the glottis. Combined with closure of the vocal cords, these actions protect the airway from **aspiration** (introduction of foreign material into the lungs) during eating and drinking.

Larynx

The **larynx** is a complex structure formed by many independent cartilaginous structures that all work together (**FIGURE 11-3**). The main laryngeal structure is the thyroid cartilage, which is suspended from the hyoid bone by the thyroid ligament. The inferior aspect of the thyroid cartilage articulates with the cricoid cartilage or cricoid ring.

The **glottic opening** is the narrowest portion of the adult trachea. Airway patency in this area depends heavily on muscle tone. Airway devices are occasionally inadvertently inserted into the piriform fossae (hollow pockets along the lateral borders of the larynx), resulting in tenting of the skin under the

jaw. The jugular notch, or suprasternal notch, is the large, visible dip located at the top of the manubrium between the neck and the two clavicles.

The Lower Airway

The function of the lower airway is to exchange oxygen and carbon dioxide. Its external boundaries are the fourth cervical vertebra and the xiphoid process, which is the narrow cartilaginous lower tip of the sternum. Internally, it spans the glottis to the pulmonary capillary membrane.

The **trachea**, or windpipe, is the conduit for air entry into the lungs. The trachea begins directly below the cricoid cartilage and descends anteriorly down the midline of the neck into the thoracic cavity. When the trachea reaches the thoracic cavity, it divides at the level of the **carina**, which externally is approximately at the level of the jugular (sternal) notch at the top of the manubrium, into the two main stem bronchi (right and left). The hollow bronchi are supported by cartilage and distribute air into the right and left lungs.

The lungs consist of the entire mass of tissue that includes the smaller bronchi, bronchioles, and alveoli (**FIGURE 11-4**). The lungs are surrounded by a serous membrane called the pleura. All lung tissue is covered with a thin, slippery outer membrane called the **visceral pleura**. The **parietal pleura** lines the inside of the thoracic cavity. A small amount of fluid is found between these two layers and serves as a lubricant to prevent friction during breathing.

On entering the lungs, each bronchus divides into increasingly smaller bronchi, which subdivide into bronchioles. The **bronchioles** are thin, hollow tubes made of smooth muscle. The tone of these smooth muscles allows the bronchioles to dilate or constrict in response to various stimuli. The smaller bronchioles branch into alveolar ducts that end at the alveolar sacs.

The alveoli, located at the end of the airway, are millions of thin-walled, balloonlike sacs that serve as the functional site for the exchange of oxygen and carbon dioxide. Surrounding each of these sacs is an intricate bed of blood vessels, known as pulmonary capillaries. Oxygen diffuses through the lining of the alveoli into the pulmonary capillaries where, depending on adequate blood volume and pressure, it is carried back to the heart for distribution to the rest of the body. At the same time, carbon

dioxide (waste) diffuses from the pulmonary capillaries into the alveoli, where it is exhaled and removed from the body. A substance called **surfactant** lines the alveoli; surfactant decreases surface tension and helps keep the alveoli expanded. If the amount of surfactant is inadequate or the alveoli are not inflated, the alveoli collapse, which results in a condition known as **atelectasis**.

The chest cage (thoracic cavity) contains the lungs, one on each side (**FIGURE 11-5**). The ribs

protect the thorax. Between each rib are intercostal muscles that can assist with breathing; however, they generally are not used unless the patient is in respiratory distress. Between the lungs is a space called the **mediastinum**, which is surrounded by tough connective tissue. This space contains the heart, the great vessels, the esophagus, the trachea, the major bronchi, and many nerves. The mediastinum effectively separates the right lung space from the left lung space.

In addition to the respiratory and circulatory structures found in the chest cage, the **phrenic nerve** travels through the chest to the diaphragm. The phrenic nerve innervates the diaphragmatic muscle, allowing it to contract. Contraction of the diaphragm occurs in a downward direction and is necessary for adequate inspiration to occur. When the phrenic nerve stops stimulation of the diaphragm, the diaphragm muscle relaxes and rises upward, allowing exhalation to occur.

Physiology of Breathing

The respiratory and cardiovascular systems work together to ensure that a constant supply of oxygen and nutrients are delivered to every cell in the body and that carbon dioxide and waste products are removed from every cell. The following sections describe the processes of **ventilation**, **oxygenation**, and **respiration**; however, you first need to

understand how the processes of breathing and circulation are connected.

As air enters the body, it passes through the vocal cords, into the glottis, and down the trachea, where it is distributed through the main stem bronchi into the bronchioles of the lungs. This occurs because negative pressure is created in the chest.

Eventually, the air reaches the alveolar sacs, where the oxygen is diffused across the alveolar membrane into the pulmonary capillaries. At the same time, carbon dioxide is diffused across this membrane and is exhaled from the body. The oxygen in the pulmonary capillaries is transported back to the heart, where it is distributed to the rest of the body.

Special Populations

Although the maneuvers, techniques, and indications for airway management are essentially the same in children as they are in adults, several anatomic differences in children make mastery of these techniques difficult.

Infants and small children have a proportionately larger occiput (posterior portion of the cranium), which causes the head to flex when the child lies supine; this position itself can cause an airway obstruction. When positioning the airway of an infant or a child, you should place a folded towel under the patient's shoulders to maintain a neutral position of the head.

Compared with adults, children have a proportionately smaller mandible and a proportionately larger tongue (**FIGURE 11-6**). Both factors increase the incidence of airway obstruction in children.

The child's epiglottis is more floppy and omega-shaped (Ω) than an adult's (**FIGURE 11-7**).

In general, the airway in infants and children is smaller and narrower at all levels. The larynx lies more

superior and anterior than an adult's. The larynx is also funnel-shaped due to the narrow, underdeveloped cricoid cartilage. In children younger than 8 years, the *narrowest* portion of the airway is at the cricoid ring. Further narrowing of the child's inherently narrow airway, such as that caused by soft-tissue swelling or foreign body aspiration, can result in a major increase in airway resistance and breathing inadequacy.

Children do not have well-developed chest musculature, and their ribs and cartilage are softer and more pliable than an adult's. As a result, the thoracic cavity cannot optimally contribute to lung expansion. Children rely heavily on their diaphragm for breathing, which moves their abdomen in and out. For this reason, infants and children are commonly referred to as belly breathers. When infants and children need to use the accessory muscles for breathing, they quickly tire and progress into respiratory distress, followed by respiratory arrest.

The heart pumps blood to the tissues of the body through a series of arteries and veins. Arteries carry oxygenated blood away from the heart and branch into arterioles and capillaries. When in the capillaries, the exchange of nutrients and waste products takes place. Oxygen and nutrients leave the capillaries and enter the cells. At the same time, waste products, such as carbon dioxide, diffuse from the cells back into the blood of the capillaries. From here, the blood travels through a series of venules that connect to larger veins. All veins (except the pulmonary vein) carry deoxygenated blood to the heart. The deoxygenated blood enters the right side of the heart through the right atrium, where it is pumped through the tricuspid valve, right ventricle, and pulmonary artery before being pumped to the lungs for oxygenation and removal of carbon dioxide. The oxygenated blood then travels through the pulmonary vein to the left atrium through the bicuspid valve, also known as the mitral valve, and into the left ventricle, where it is again pumped to the rest of the body. Refer to Chapter 7, *The Human Body*, for an illustration of this process.

It is important to understand that the respiratory and circulatory systems work together to facilitate oxygen delivery to the tissues of the body (TABLE 11-1). When one of these systems is compromised, oxygen delivery is not effective and cellular death could result.

Every cell in the body needs a constant supply of oxygen to survive. Whereas some tissues are more resilient than others, eventually all cells will die if deprived of oxygen (FIGURE 11-8). To deliver adequate amounts of oxygen to the tissues of the

FIGURE 11-8 Cells need a constant supply of oxygen to survive. Some cells may be severely or permanently damaged after 4 to 6 minutes without oxygen.

© Jones & Bartlett Learning.

body, sufficient levels of external ventilation and perfusion—circulation of blood within an organ or tissue in adequate amounts to meet the cells' current needs—must take place.

Ventilation

Pulmonary ventilation, the process of moving air into and out of the lungs, is necessary for oxygenation and respiration to occur. Adequate, continuous ventilation is essential for life and, therefore, is one of the highest priorities in treating any patient. If a patient is not breathing or is breathing inadequately, you must immediately intervene to ensure adequate ventilation.

Inhalation

The active, muscular part of breathing is called **inhalation**. When a person inhales, air enters the body through the mouth and nose and moves to the trachea. This air travels to and from the lungs, filling and emptying the alveoli. During inhalation, the diaphragm and intercostal muscles contract. When the diaphragm contracts, it moves down slightly and enlarges the thoracic cage from top to bottom, and when the intercostal muscles contract, they lift the ribs up and out. The combined actions of these structures enlarge the thorax in all directions, creating a negative pressure that draws air in. Maximum inspiration occurs when the diaphragm and intercostal muscles are contracted and the lungs fill with air.

The lungs have no muscle tissue; therefore, they cannot move on their own. They need the help of other structures to be able to expand and contract

TABLE 11-1 Ventilation, Oxygenation, and Respiration

during inhalation and exhalation. Therefore, the ability of the lungs to function properly is dependent on the movement of the chest and supporting structures. These structures include the thorax, the thoracic cage (chest), the diaphragm, the intercostal muscles, and the accessory muscles of breathing. Accessory muscles are secondary muscles of respiration.

The diaphragm is a specialized skeletal muscle. Innervated by the phrenic nerve, the diaphragm is attached to the costal arch and the vertebrae and functions as both a voluntary and involuntary muscle. It acts as a voluntary muscle when you are taking a deep breath, coughing, or holding your breath—all actions that are under voluntary control. However, unlike other skeletal or voluntary muscles, the diaphragm also performs an automatic function. Breathing continues during sleep and at all other times. Although you can hold your breath or temporarily breathe more quickly or slowly, you cannot continue these variations in breathing indefinitely. When the concentration of carbon dioxide rises within the blood, the autonomic regulation of breathing resumes under the control of the brainstem.

Words of Wisdom

Ventilation is the physical act of moving air in and out of the lungs. Ventilation is required for adequate respiration. If ventilation is adequate, other problems may hinder respiration. Examples of conditions that produce interruptions of ventilation include trauma such as a flail chest, foreign body airway obstruction, and an injury to the spinal cord that disrupts the function of the phrenic nerve that innervates the diaphragm.

Partial pressure is the term used to describe the amount of gas in air or dissolved in fluid, such as blood. Partial pressure is measured in millimeters of mercury (mm Hg). The partial pressure of oxygen in air residing in the alveoli is 104 mm Hg. Carbon dioxide enters the alveoli from the blood and causes a partial pressure of carbon dioxide of 40 mm Hg.

Deoxygenated arterial blood from the right side of the heart has a partial pressure of oxygen (P_{aO_2}) that is lower than the partial pressure of oxygen

in the alveoli. The body attempts to equalize the partial pressure, which results in oxygen diffusion across the membrane into the blood; carbon dioxide diffuses into the alveoli and is eliminated as waste during exhalation. Oxygen and carbon dioxide both diffuse until partial pressures in the alveoli and blood are equal. This process occurs in reverse when the arterial blood reaches the tissues. Oxygen diffuses into the tissue fluid and then into the cells, and carbon dioxide diffuses out of the cells into the tissue fluid and blood.

The air pressure outside the body, called the atmospheric pressure, is normally higher than the air pressure within the thorax. During inhalation, the thoracic cage expands and the air pressure within the thorax decreases, creating a slight vacuum. This pulls air in through the trachea, causing the lungs to fill. When the air pressure outside equals the air pressure inside, air stops moving. Gases, such as oxygen, will move from an area of higher pressure to an area of lower pressure until the pressures are equal. At this point, the air stops moving, and inhalation stops.

It may help you to understand this if you think of the thoracic cage as a bell jar in which balloons are suspended. In this example, the balloons are the lungs. The base of the jar is the diaphragm, which moves up and down slightly with each breath. The ribs, which are the sides of the jar, maintain the shape of the chest. The only opening into the jar is a small tube at the top, similar to the trachea. During inhalation, the bottom of the jar moves down slightly, causing a decrease in pressure in the jar and creating a slight vacuum. As a result, the balloons fill with air (**FIGURE 11-9**).

The entire process of **inspiration** is focused on delivering oxygen to the alveoli. However, not all of the air you breathe actually reaches the alveoli. **TABLE 11-2** reviews terminology as it relates to the process of inspiration and ventilation.

It is important to note that variations in tidal volume, **respiratory rate** (the number of times a person breathes in 1 minute), or both will affect the minute volume. For example, if a patient is breathing at a rate of 12 breaths/min, but the tidal volume is reduced (shallow breathing), minute volume will decrease. Likewise, if a patient is breathing at a rate of 12 breaths/min and the tidal volume increases (deep breathing), minute volume will increase.

FIGURE 11-9 The mechanism of ventilation can be illustrated by a bell jar. **A.** Inhalation and chest expansion, anatomic (left) and bell jar (right). **B.** Exhalation and chest contraction, anatomic (left) and bell jar (right).

© Jones & Bartlett Learning.

Exhalation

Unlike inhalation, **exhalation** does not normally require muscular effort; therefore, it is a passive process. As the chest expands, mechanical receptors, known as stretch receptors, in the chest wall and bronchioles send a signal to the apneustic center via the vagus nerve to inhibit the inspiratory center, and exhalation occurs. This feedback loop, a combination of mechanical and neural control, is known as the **Hering-Breuer reflex** and terminates inhalation to prevent overexpansion of the lungs. The diaphragm and intercostal muscles relax, which increases intrapulmonary pressure. The natural elasticity, or recoil, of the lungs passively removes the air. When the size of the thoracic cage decreases, air in the lungs is compressed into a smaller space. The air pressure within the thorax then becomes higher than the outside pressure, and the air is pushed out through the trachea. Maximum **expiration** occurs when the diaphragm

TABLE 11-2 Ventilation Terminology

Term	Definition
Tidal volume	The amount of air (in milliliters) that is moved in or out of the lungs during one breath.
Residual volume	The air that remains in the lungs after maximal expiration.
Alveolar ventilation	The volume of air that reaches the alveoli; calculated by subtracting the amount of dead space air from the tidal volume.
Minute volume	The volume of air moved through the lungs in 1 minute; calculated by multiplying tidal volume and respiratory rate.
Alveolar minute volume	The volume of air moved through the lungs in 1 minute minus the dead space; calculated by multiplying tidal volume (minus dead space) and respiratory rate.
Vital capacity	The amount of air that can be forcibly expelled from the lungs after breathing in as deeply as possible.
Dead space	The portion of the tidal volume that does not reach alveoli and thus does not participate in gas exchange.

© Jones & Bartlett Learning.

and intercostal muscles relax and air is exhaled forcefully as opposed to the normal passive process.

Remember that air will reach the lungs only if it travels through the trachea. This is why clearing and maintaining an open airway is so important. Clearing the airway means removing obstructing material, tissue, or fluids from the nose, mouth, and throat. Maintaining the airway means keeping the airway **patent** so that air can enter and leave the lungs freely (**FIGURE 11-10**).

Air may also pass into the chest cavity through an abnormal opening in the throat or chest wall as a result of trauma, remaining outside the bronchi and never reaching the alveoli. In later chapters, you will learn how to recognize and manage these potentially life-threatening conditions.

FIGURE 11-10 Air reaches the lungs only if it travels through the trachea. Maintaining the airway means keeping the airway patent so that air can enter and leave the lungs freely.

Regulation of Ventilation

The body's need for oxygen is dynamic. The respiratory system must be able to accommodate the changes in oxygen demand by altering the rate and depth of ventilation. The regulation of ventilation involves a complex series of receptors and feedback loops that sense gas concentrations in the body fluids and send messages to the respiratory center in the brain to adjust the rate and depth of ventilation accordingly. For most people, the drive to breathe is based on pH changes (related to the carbon dioxide level) in the blood and CSF. In healthy people, when the oxygen level rises, the respiratory center suspends respiration until a rising carbon dioxide level stimulates the respiratory center to begin breathing again.

Oxygenation

Oxygenation is the process of loading oxygen molecules onto hemoglobin molecules in the

bloodstream. Adequate oxygenation is required for internal respiration to take place; however, it does not guarantee internal respiration is taking place. Oxygenation requires that the air used for ventilation contains an adequate percentage of oxygen. Although a person generally cannot oxygenate without ventilation, it is possible to ventilate without oxygenation. This situation occurs in places where the oxygen level in the breathing air has been depleted, such as in mines and confined spaces. Ventilation without adequate oxygenation also occurs in climbers who ascend too quickly to an altitude with inadequate atmospheric pressure. At high altitudes, the percentage of oxygen remains the same, but the atmospheric pressure makes it difficult to adequately bring sufficient amounts of oxygen into the body.

Respiration

All living cells perform a specific function and need energy to survive. Cells take energy from nutrients through a series of chemical processes. The name given to describe these processes is **metabolism** (**cellular respiration**). During metabolism, each cell combines nutrients (such as sugar) and oxygen and produces energy and waste products, primarily water and carbon dioxide. Each cell in the body requires a continuous supply of oxygen and a regular means of disposing of waste (carbon dioxide). The body provides for these requirements through respiration.

Respiration is the process of exchanging oxygen and carbon dioxide. This exchange occurs by diffusion, a process in which a gas moves from an area of greater concentration to an area of lower concentration. In the body, gases diffuse rapidly across a short distance of only micrometers.

External Respiration

External respiration (pulmonary respiration) is the process of breathing fresh air into the respiratory system and exchanging oxygen and carbon dioxide between the alveoli and the blood in the pulmonary capillaries (**FIGURE 11-11**).

Fresh air that is inspired into the lungs contains about 21% oxygen, 78% nitrogen, and 0.3% carbon dioxide. As this air reaches the alveoli, it comes into contact with surfactant. As discussed, surfactant reduces surface tension within the alveoli and keeps

FIGURE 11-11 External respiration.

© Jones & Bartlett Learning.

them expanded, making it easier for the gas exchange between oxygen and carbon dioxide to take place. It is important to remember that although adequate ventilation is necessary for external respiration to take place, it does not guarantee that external respiration is being achieved.

After the oxygen crosses the alveolar-capillary membrane, it is bound to hemoglobin, an iron-containing protein molecule that has a great affinity for oxygen molecules, that is found in red blood cells. Hemoglobin molecules low in oxygen concentration are pumped from the right side of the heart into the capillaries of the pulmonary circulation. The capillaries surround alveoli containing high concentrations of oxygen (from inspired air). The hemoglobin molecules pick up fresh oxygen as it crosses the alveolar membrane and transport it back to the left side of the heart, where it is pumped out to the rest of the body. Under normal conditions, 96% to 100% of the hemoglobin receptor sites contain oxygen.

Words of Wisdom

The blood does not use all the inhaled oxygen as it passes through the body. The air that we exhale contains approximately 16% oxygen and 3% to 5% carbon dioxide; the rest is nitrogen. Therefore, when you provide mouth-to-mouth (or mask) ventilation to a patient who is not breathing, the patient is receiving a 16% concentration of oxygen with each of your exhaled breaths.

FIGURE 11-12 Internal respiration.

© Jones & Bartlett Learning.

Internal Respiration

The exchange of oxygen and carbon dioxide between the systemic circulatory system and the cells of the body is called **internal respiration**. As blood travels through the body, it supplies oxygen and nutrients to various tissues and cells. As the oxygenated blood travels through the arteries and capillaries, the oxygen passes from the blood in the capillaries to tissue cells, while carbon dioxide and cell waste pass in the opposite direction: from tissue cells through capillaries and into the veins (**FIGURE 11-12**).

In the presence of oxygen, the mitochondria of the cells convert glucose into energy using a process known as **aerobic metabolism**. Energy in the form of adenosine triphosphate (ATP) is produced through a series of processes known as the Krebs cycle and oxidative phosphorylation. Together, these chemical processes yield nearly 40 molecules of energy-rich ATP for each molecule of glucose metabolized. Without adequate oxygen, the cells do not completely convert glucose into energy, and lactic acid and other toxins accumulate in the cell. This process, **anaerobic metabolism**, cannot meet the metabolic demands of the cell. Although another intracellular process, glycolysis, also contributes to ATP production and does not require oxygen, this process results in less ATP production, and lactic acid waste products and toxins are produced. If this process is not corrected, the cells will eventually die. Therefore, adequate levels of perfusion (circulation of blood within an organ or tissue)

and external ventilation must be present for aerobic internal respiration to take place. However, although these elements are necessary for internal respiration, they do not guarantee that aerobic internal respiration will take place.

When the mitochondria within each cell use oxygen to convert glucose to energy, carbon dioxide (the main waste product) accumulates in the cell. Carbon dioxide is then transported through the circulatory system and back to the lungs for exhalation.

When oxygen is not present, anaerobic metabolism occurs. It creates a series of events that will eventually result in cellular death. Initially, cells become hypoxic, and as stores of glucose are used up, lactic acid, which is the by-product of glycolysis, remains. The increasing acidic environment destroys the cellular proteins, which in turn results in cellular death and infarction of tissue as more cells become ischemic and then necrotic.

Understanding the process of ventilation, oxygenation, and respiration is an important concept for AEMTs. The overall goal of these mechanisms is to deliver an adequate supply of oxygen to the cells of the body. When one of these processes fails or becomes disrupted, cells will die. By recognizing the signs and symptoms of inadequate tissue perfusion and oxygenation, you can immediately intervene and correct a potentially life-threatening condition.

Neural Control

The neural control of breathing originates in the brain and brainstem. Primary control comes from the medulla and pons. The medulla is the primary involuntary respiratory center. It is connected to the respiratory muscles by the vagus nerve. The medullary respiratory centers control the rate, depth, and rhythm of breathing in a negative feedback interaction with centers in the pons.

The apneustic center of the pons is the secondary control center if the medulla fails to initiate respiration. The apneustic center influences the respiratory rate by increasing the number of inspirations per minute. This is balanced by the pneumotaxic center, which has an inhibitory influence on inspiration. The respiratory rate, therefore, results from the interaction between these two centers. In times of increased demand, the pneumotaxic

center decreases its influence, thereby increasing the respiratory rate.

Chemical Stimuli

The goal of the respiratory system is to keep the blood's concentrations of oxygen and carbon dioxide and its acid-base balance within very narrow normal ranges. The body has many receptors that monitor variables and provide feedback to the respiratory centers to modify the respiratory rate and depth based on the body's needs. These **chemoreceptors** have important effects on respiratory rate and depth.

Chemoreceptors that constantly monitor the chemical composition of body fluids are located throughout the body to provide feedback on many metabolic processes. Three sets of chemoreceptors affect respiratory function. The first two, which monitor the carbon dioxide level in the blood and the pH of the CSF, have a much greater effect on ventilatory depth and rate than does the third.

The chemoreceptors that measure the amount of carbon dioxide in arterial blood are located in the carotid bodies and the aortic arch. These receptors sense minute changes in the carbon dioxide level and send signals to the respiratory center via the glossopharyngeal nerve (9th cranial nerve) and the vagus nerve (10th cranial nerve).

Central chemoreceptors, which constantly monitor the pH of the CSF, are located adjacent to the respiratory centers in the medulla. The acidity of the CSF is an indirect measure of the amount of carbon dioxide in arterial blood because the carbon dioxide in the blood readily diffuses across the blood-brain barrier and combines with water to form carbonic acid (H_2CO_3). The carbonic acid dissociates, and the pH decreases as the hydrogen ion (H^+) concentration increases. An increase in the acidity of CSF triggers the central chemoreceptors to increase the rate and depth of respiration. These central chemoreceptors are sensitive to small changes in pH and provide for fine-tuning of the body's acid-base balance.

Although the primary control of ventilation is the pH of the CSF, the amount of oxygen dissolved in the plasma (PaO_2) has a secondary and protective role. The chemoreceptors located in the aortic arch and carotid bodies also respond to decreases in PaO_2 by sending messages to the respiratory control

center to increase respiration. Under normal conditions, these chemoreceptors serve as a backup to the primary control of ventilation, which is based on the level of carbon dioxide in the blood and the pH of the CSF.

When serum carbon dioxide or hydrogen ion levels increase because of medical or traumatic conditions involving the respiratory system, chemoreceptors stimulate the dorsal and ventral respiratory groups in the medulla to increase the respiratory rate, thus removing more carbon dioxide or acid from the body. The **dorsal respiratory group** is responsible for initiating inspiration based on the information received from the chemoreceptors. The **ventral respiratory group** is primarily responsible for motor control of the inspiratory and expiratory muscles.

Pathophysiology of Respiration

Multiple conditions inhibit the body's ability to effectively deliver oxygen to the cells. Disruption of pulmonary ventilation, oxygenation, and respiration will cause immediate effects on the body. As an AEMT, you need to recognize these conditions and correct them immediately.

Hypoxia

Failure to meet the body's needs for oxygen may result in **hypoxia**. Hypoxia is an extremely dangerous condition in which the tissues and cells of the body do not get enough oxygen. If this process is not corrected, patients may die quickly.

Patients with chronic obstructive pulmonary disease (COPD) have difficulty eliminating carbon dioxide through exhalation; thus, they always have higher levels of carbon dioxide. This potentially can alter their drive for breathing. The theory is that respiratory centers in the brain gradually accommodate to a high level of carbon dioxide. In patients with COPD in the end stage of their disease, the body uses a "backup system" to control breathing. This theory of secondary control of breathing, called **hypoxic drive**, stimulates breathing when the arterial oxygen level falls. However, the nerves in the brain, the walls of the aorta, and the carotid arteries that act as oxygen sensors are easily satisfied with a minimal level of oxygen. Therefore, the hypoxic

drive is much less sensitive and less powerful than the carbon dioxide sensors in the brainstem.

Hypoxic drive is typically found in end-stage COPD and not in the patient with a recent diagnosis. Providing high concentrations of oxygen could potentially negatively affect the body's drive to breathe in patients who are dependent on hypoxic drive. This effect is rare, however, and easily addressed with coaching or ventilator assistance. A high concentration of oxygen should never be withheld from any patient who needs it.

Patients who are breathing inadequately will show varying signs and symptoms of hypoxia. The onset and degree of tissue damage caused by hypoxia often depend on the quality of ventilations. Early signs of hypoxia include restlessness, irritability, apprehension, fast heart rate (tachycardia), and anxiety. Late signs of hypoxia include mental status changes, a weak (thready) pulse, and cyanosis. Responsive patients will report shortness of breath (**dyspnea**) and may not be able to talk in complete sentences. You should administer supplemental oxygen to a patient with respiratory distress before signs and symptoms of hypoxia appear.

Words of Wisdom

A patient who is breathing inadequately (hypoventilating) requires supplemental oxygen regardless of history. Withholding oxygen from a patient with COPD in an attempt to preserve the hypoxic drive may be detrimental. If vital organs are not perfused, cells and tissue may die, resulting in irreversible damage. Even after the cause of the problem is addressed, if substantial damage has occurred, the patient may not recover. By ventilating a hypoxic patient, vital organs are perfused. If the hypoxic drive is eliminated, organs are still oxygenated. After the cause of the original problem has been corrected, the patient can be weaned off the ventilator and may return to a normal, productive life.

Ventilation-Perfusion Ratio and Mismatch

The lungs have a functional role of placing ambient (room) air in proximity to circulating blood to permit gas exchange by simple diffusion. To accomplish this action, air and blood flow must be directed to the same place at the same time. In other

words, ventilation and perfusion must be matched. A failure to match ventilation and perfusion, or **$\dot{V}/\dot{Q}$ mismatch**, contributes to most abnormalities in oxygen and carbon dioxide exchange.

In most people, the normal resting minute ventilation is approximately 6 L/min. Approximately one-third of this volume fills dead space; therefore, resting alveolar ventilation is approximately 4 L/min. However, pulmonary artery blood flow is approximately 5 L/min. This yields an overall ratio of ventilation to perfusion of four-fifths L/min, or 0.8 L/min. Because neither ventilation nor perfusion is distributed equally, both are distributed to dependent regions of the lungs at rest. However, the increase in gravity-dependent flow is more marked with perfusion (blood) than with ventilation (air). Hence, the ratio of ventilation to perfusion is highest at the apex (top) of the lung and lowest at the base (bottom).

When ventilation is compromised but perfusion continues, blood passes over some alveolar membranes without gas exchange taking place; therefore, not all alveoli are enriched with oxygen. This results in a lack of oxygen diffusing across the membrane and into the circulatory system. Along the same lines, carbon dioxide is also unable to diffuse across the membrane and is recirculated in the bloodstream. The $\dot{V}/\dot{Q}$ mismatch that results limits the ability of the lungs to oxygenate the blood and to filter carbon dioxide from the blood. When this affects a large portion of the lung, the result can be fatal.

Similar problems can occur when perfusion across the alveolar membrane is disrupted. Although the alveoli are filled with fresh oxygen, disruption in blood flow does not allow for exchange of gases across the membrane in affected areas of the lung. The result of inadequate perfusion is less oxygen absorption in the bloodstream and less carbon dioxide removal. This $\dot{V}/\dot{Q}$ ratio mismatch can also result in hypoxia, and when severe, the patient needs immediate intervention to prevent further damage or death.

Factors Affecting Ventilation

Maintaining a patent airway is critical to the delivery of oxygen to the tissues of the body. Many intrinsic and extrinsic factors cause airway obstruction. Intrinsic conditions such as infections, allergic

reactions, and unresponsiveness (possibly resulting in airway obstruction by the tongue) can cause substantial restrictions on the ability to maintain an open airway. Swelling from infections and allergic reactions can be fatal if not aggressively managed with medications and, possibly, advanced airway management techniques. The tongue is the most common airway obstruction in an unresponsive patient. This airway obstruction, although easily corrected, can result in hypoxia and hinder adequate tissue perfusion. Snoring respirations and an improper position of the head and/or neck are good indicators that the tongue may be obstructing the airway. Prompt correction of this obstruction is necessary for adequate ventilation and oxygenation.

Some factors affecting pulmonary ventilation are not necessarily directly part of the respiratory system. The central and peripheral nervous systems have key roles in the regulation of breathing. Interruptions to these systems can have a drastic effect on the ability to breathe efficiently. Medications that depress the central nervous system lower the respiratory rate and tidal volume. This lower rate and volume will decrease the overall minute volume and alveolar ventilation. As a result, the amount of carbon dioxide in the respiratory and circulatory systems is increased, resulting in an overall increase of the carbon dioxide level in the bloodstream, known as **hypercapnia**. Trauma to the head and spinal cord can also interrupt nervous control of ventilation, resulting in decreased respiratory function and even failure. Neuromuscular disorders, such as muscular dystrophy, can also affect the ability of the nervous system to control breathing. Muscular dystrophy causes degeneration of muscle fibers, slowing motor development, and loss of muscle contractility. Curvature of the spine is also likely in patients with muscular dystrophy and can impair pulmonary function.

Patients with allergic reactions might have not only a potential airway obstruction from swelling (angioedema), but also a decrease in pulmonary ventilation from bronchoconstriction. As the bronchioles constrict, air is forced through smaller lumens resulting in decreased ventilation. Bronchoconstriction is also associated with conditions such as COPD and asthma.

Extrinsic factors affecting pulmonary ventilation can include trauma and foreign body airway obstruction. Trauma to the airway or chest requires

immediate evaluation and intervention. Blunt or penetrating trauma and burns can disrupt airflow through the trachea and into the lungs, quickly resulting in oxygenation deficiencies. In addition, trauma to the chest wall can result in structural damage to the thorax, resulting in inadequate pulmonary ventilation. For example, a patient with numerous rib fractures or a flail chest may purposely breathe shallowly in an attempt to alleviate the pain caused by the injury. This practice is called respiratory splinting and can result in decreased pulmonary ventilation. Swelling, punctures, and lung tissue bruising can all have a tremendous effect on the ability to deliver oxygen to the alveoli and into the bloodstream. Proper airway management and ventilatory support are crucial to the outcome in these situations.

If carbon dioxide production exceeds the body's ability to eliminate it by ventilation, then the partial pressure of carbon dioxide (P_{aCO_2}) rises, resulting in hypoventilation (slow and/or shallow breathing). Theoretically, hypoventilation can occur in two ways: either carbon dioxide production can exceed the body's ability to eliminate it, or carbon dioxide elimination can be depressed to the extent that it no longer keeps up with normal metabolism.

At the other extreme is **hyperventilation** (rapid and/or deep breathing), which occurs when carbon dioxide elimination exceeds carbon dioxide production. For example, a patient experiencing an anxiety attack tends to breathe very deeply and rapidly, thus eliminating carbon dioxide at a rate faster than the body produces it. The level of carbon dioxide in the patient's blood then falls below normal, and the patient experiences symptoms such as dizziness and numbness or tingling in the face and extremities.

Hypoventilation and hyperventilation could represent the body's attempt to compensate for various abnormal conditions. For example, if the pH of the blood is too high (**alkalosis**), the patient's breathing may become slow and/or shallow in an attempt to retain carbon dioxide (and therefore, hydrogen ions $[H^+]$) in an attempt to decrease the pH. Conversely, hyperventilation could be a compensatory response of the body to a decrease in the pH of the blood (**acidosis**), such as what occurs with hyperglycemic ketoacidosis or aspirin overdose.

In addition to factors discussed thus far, decreases or increases in minute volume can result in

TABLE 11-3 Carbon Dioxide Balance

	Hypoventilation	Hyperventilation
Minute volume	↓	↑
CO ₂ elimination	↓	↑
Paco ₂	↑ (hypercapnia)	↓ (hypocapnia)

Abbreviations: CO₂, carbon dioxide; Paco₂, partial pressure of carbon dioxide

© Jones & Bartlett Learning.

problems with carbon dioxide levels in the blood (**TABLE 11-3**). A decrease in the minute volume decreases carbon dioxide elimination, resulting in a buildup of carbon dioxide in the blood (hypercapnia). An increase in the minute volume increases carbon dioxide elimination, which lowers the carbon dioxide content of the blood (hypocapnia).

Factors Affecting Oxygenation and Respiration

External elements in the environment can affect the overall process of respiration. For proper respiration to take place at the cellular level, both oxygenation and perfusion need to function efficiently.

External Factors

Adequate respiration requires proper ventilation and oxygenation. External factors such as atmospheric pressure and the partial pressure of oxygen (P_{aO_2}) in the ambient air have a key role in the overall process of respiration. At high altitudes, the percentage of oxygen remains the same, but the partial pressure decreases because the total atmospheric pressure decreases. The low P_{aO_2} can make it difficult (or impossible) to adequately oxygenate tissue, thus interrupting internal respiration. In addition, closed environments, such as mines and trenches, may also have decreases in ambient oxygen, resulting in poor oxygenation and respiration.

Carbon monoxide, along with other toxic gases, displaces oxygen in the environment and makes proper oxygenation and respiration difficult. Particularly, carbon monoxide has a much greater affinity for hemoglobin than does oxygen (200 to 250 times greater). The attachment of carbon monoxide molecules to the hemoglobin molecules, which forms

carboxyhemoglobin (COHb), inhibits the proper transport of oxygen to tissues and can cause false pulse oximeter readings.

Internal Factors

Conditions that reduce the surface area for gas exchange also decrease the body's oxygen supply, resulting in inadequate tissue perfusion. Medical conditions such as pneumonia, **pulmonary edema**, and COPD may also result in a disturbance of cellular metabolism. These conditions decrease the surface area of the alveoli by damaging the alveoli or by resulting in an accumulation of fluid in the lungs.

Nonfunctional alveoli inhibit the diffusion of oxygen and carbon dioxide. As a result, blood entering the lungs from the right side of the heart bypasses the alveoli and returns to the left side of the heart in an unoxygenated state, a condition called **intrapulmonary shunting**.

Patients who are submerged in water and patients with pulmonary edema have fluid in the alveoli. This accumulation of fluid inhibits adequate gas exchange at the alveolar membrane and results in decreased oxygenation and respiration. In addition, exposure to certain environmental conditions (such as high altitudes) or occupational hazards (such as epoxy resins) can result in fluid accumulation in the alveoli over time, resulting in an overall decrease in respiration. Respirations increase or decrease based on the body's need at any given time. As body temperature rises, the number of respirations increase in response to the increased metabolic activity. Certain medications cause the respiratory rate to increase or decrease, depending on their physiologic action. Pain and strong emotions can also increase respirations. Hypoxia, which is a powerful stimulus to breathe, increases respirations in an effort to bring in more oxygen. Conversely, to eliminate carbon dioxide from the body, respirations increase when carbon dioxide production is increased. Respirations decrease as metabolism slows, such as during sleep.

Other conditions that affect the cells of the body include hypoxia, hypoglycemia (low blood glucose level), and infection. As oxygen and glucose levels decrease, the body is unable to maintain a homeostatic balance regarding energy production. At this point, the energy production cannot meet the needs of the body, and cellular death is likely if the condition is not corrected. Infection also

increases the metabolic needs of the body and disrupts homeostasis. If not corrected, the cells will die as well. If the levels of the hormone insulin decrease in the body, then the cellular uptake of glucose will decrease. Without sufficient glucose, the cells will metabolize fatty acids, resulting in ketoacidosis—a form of metabolic acidosis.

Words of Wisdom

During normal breathing, the negative pressure created by each breath increases venous return of blood to the heart. Just as negative intrathoracic pressure draws air into the chest cavity through the airway (**negative-pressure ventilation**), the same pressure also draws venous blood back to the heart from the head (via the superior vena cava) and abdomen (via the inferior vena cava).

When patients transition from negative-pressure ventilation to positive-pressure ventilation (the forcing of air into the lungs [ie, bag-mask ventilation]), they lose this stimulus for venous return, and some patients may experience decreased cardiac output and hypotension as a result. The increased intrathoracic pressure caused by positive-pressure ventilation creates a pressure gradient against which the heart must pump. This process also increases the afterload (the amount of resistance against which the ventricle must contract), which can further decrease cardiac output. The greater the pressure used to ventilate an apneic or a hypoventilating patient, the greater the decrease in **preload** (the volume of blood that returns to the heart), which occurs when the heart is literally squeezed by increased intrathoracic pressure.

Patients who are hypotensive, in shock, or are otherwise hemodynamically unstable may experience profound changes in blood pressure as a result of the hemodynamic effects of positive-pressure ventilation. The best way to minimize this complication is to ventilate the patient for a period of 1 second (just enough to cause visible chest rise) and avoid ventilating the patient too fast.

Circulatory Compromise

For respiration to take place, the circulatory system must function efficiently to deliver oxygen to the tissues of the body. When this system becomes compromised, perfusion becomes inadequate and the body's oxygen demands will not be met.

Obstruction of blood flow to individual cells and tissue is typically related to trauma emergencies.

Conditions you may encounter include pulmonary embolism, a simple or tension **pneumothorax**, open pneumothorax (sucking chest wound), hemothorax, and hemopneumothorax. All of these conditions inhibit gas exchange at the tissue level as a result of their effects on the respiratory and circulatory systems. In addition, conditions such as heart failure and cardiac tamponade inhibit the ability of the heart to effectively pump oxygenated blood to the tissues.

Blood loss and anemia (a deficiency of red blood cells) reduce the oxygen-carrying capacity of the blood. Without sufficient circulating red blood cells, not enough hemoglobin molecules are available to bind with oxygen.

When the body is in a state of shock, oxygen is not delivered to the cells efficiently. Hemorrhagic shock (a form of **hypovolemic shock**) is an abnormal decrease in blood volume that causes inadequate oxygen delivery to the body. In contrast, **vasodilatory shock** is not determined by the amount of circulating blood, but by the size of the blood vessels. As the diameter of the blood vessels increases, the blood pressure in the circulatory system decreases; oxygen is not delivered to the tissues in an effective manner. Both forms of shock result in poor tissue perfusion that results in anaerobic

metabolism. You should aggressively treat any patient suspected of being in shock to prevent further interruptions in tissue perfusion.

Acid-Base Balance

Both hypoventilation and hyperventilation, along with hypoxia, cause disruptions in the acid-base balance in the body that may result in rapid deterioration and death. The respiratory system and the renal system have roles in maintaining homeostasis in the body. Homeostasis is a tendency toward stability in the body's internal environment and requires a balance between the acids and bases in the body. When there is excess acid in the body, the fastest way to eliminate it is through the respiratory system. Excess acid can be expelled as carbon dioxide from the lungs. Conversely, slowing respirations will increase the level of carbon dioxide. The renal system regulates pH by filtering out more hydrogen and retaining bicarbonate when needed, or doing the reverse. The fastest way the body can eliminate excess H^+ ions is to create water and carbon dioxide, which can be expelled from the lungs.

Anything that inhibits respiratory function can result in acid retention and acidosis. Any time a patient is in respiratory distress or is unable to breathe,

YOU are the Provider

Part 2

As you approach the patient, you note snoring respirations approximately every 10 to 12 seconds, with cyanosis around the patient's lips and nail beds. You attempt to speak to the patient, but he responds with only a low moaning sound when you do a sternal rub. You direct your partner to immediately open the airway and establish bag-mask ventilations at a rate of 10 breaths/min, with supplemental oxygen. As you perform your primary survey of the patient, you note no abnormal findings beyond his cyanosis, and no readily identifiable cause for his hypoxia and bradypnea. You apply your pulse oximeter and obtain a reading of 78%.

Recording Time: 1 Minute

Appearance	Poor
Level of consciousness	Moans to pressure stimulation
Airway	Snoring respirations
Breathing	Shallow, slow
Circulation	Cool, clammy, cyanotic

- Which acid-base disorder do you suspect this patient is experiencing?
- How does the pulse oximeter guide your treatment of this patient?

acidosis quickly develops. Acidosis can develop as a result of abnormal respiratory function (such as with **bradypnea**, labored breathing, or shallow breathing [reduced tidal volume]). Alkalosis can develop if the respiratory rate is too high (**tachypnea**) or the volume too great.

Recall that the four main clinical presentations of acid-base disorders are as follows:

- **Respiratory acidosis**
- **Respiratory alkalosis**
- **Metabolic acidosis**
- **Metabolic alkalosis**

Fluctuations in pH due to the available bicarbonate level result in metabolic acidosis or alkalosis. Fluctuations in pH due to respiratory disorders result in respiratory acidosis or alkalosis. The focus here is on respiratory acidosis and respiratory alkalosis.

Acid-base disorders that are not immediately correctable by the body's buffering systems initiate compensatory mechanisms to help return levels to normal. For example, metabolic acidosis may create respiratory alkalosis as a compensatory response. Often, patient treatment involves treating more than one form of acid-base imbalance.

Treatment for the classic hyperventilation syndrome focuses on restoring the normal respiratory rate to increase the carbon dioxide level. However, increasing the carbon dioxide level can aggravate other more serious medical conditions that cause hyperventilation. Therefore, you must carefully evaluate the patient to determine the underlying cause of the hyperventilation before you attempt to correct it.

Patient Assessment: Airway Evaluation

Recognizing Adequate Breathing

You can think of a normal breathing pattern as a bellows system. Breathing should appear easy, not labored. As with a bellows used to move air to start a fire, breathing should be a smooth flow of air into and out of the lungs. A patient with adequate breathing should be able to speak in full sentences and in a normal voice. Generally, if you can see or hear a patient breathe, there is a problem.

Normal respirations in an adult are characterized by a rate of between 12 and 20 breaths/min

TABLE 11-4 Normal Respiratory Rate Ranges

Age	Range (breaths/min)
Adults	12 to 20
Children (ages 1 to 18 years)	12 to 37
Infants (ages 1 month to 1 year)	30 to 53

Pediatric data from: American Heart Association (AHA). Vital signs in children. In: *Pediatric Advanced Life Support*. Dallas, TX: AHA; 2015.

with adequate depth (tidal volume), a regular pattern of inhalation and exhalation, and clear and equal **bilateral** breath sounds (on both sides of the chest) (**TABLE 11-4**). Breathing at rest should be effortless; changes may be subtle in rate or regularity.

Recognizing Inadequate Breathing

An adult patient who is breathing at a rate of fewer than 12 breaths/min or more than 20 breaths/min should be evaluated for other signs of inadequate breathing, such as shallow breathing (reduced tidal volume), an irregular pattern of breathing, altered mentation, or abnormal breath sounds. Irregular respiratory patterns are clinically important until proven otherwise.

Words of Wisdom

Recognition of an extremely rapid rate, an incredibly slow rate, any unusual respiratory pattern, or poor tidal volume should immediately prompt you to consider bag-mask ventilations if the patient will tolerate it.

Patients with respiratory distress often compensate with preferential positioning, such as an upright sniffing position (in which the patient is sitting up, with the head moved forward until the earlobes are on the same vertical plane as the manubrium of the sternum), or a tripod position (in which the patient is sitting up and leaning forward with elbows bent). A patient experiencing breathing difficulty will avoid a supine position because this position typically increases respiratory distress.

Respiratory distress may be the result of upper and/or lower airway obstruction, inadequate ventilation, impairment of the respiratory muscles, or impairment of the nervous system. Any difficulty in respiratory rate, regularity, or effort is defined as dyspnea. Dyspnea may be the result of or result in **hypoxemia**—a deficiency of oxygen in the arterial blood. If left untreated, hypoxemia will progress to hypoxia (lack of oxygen to the body's cells and tissues). Untreated hypoxia will result in anoxia and death of the body's cells and tissues.

Words of Wisdom

Hypoxemia is defined as a low level of oxygen in arterial blood. *Hypoxia*, as discussed earlier, is a deficiency of oxygen at the tissue and cellular levels. Although these terms are often used interchangeably, they are different processes. Hypoxemia can often be reversed by administering supplemental oxygen, whereas hypoxia may require more aggressive oxygenation and, in some cases, metabolic correction. Left untreated, hypoxia will result in **anoxia**—a lack of oxygen that results in tissue and cellular death.

Recognition and treatment of dyspnea are crucial to patient survival. Careful assessment and treatment of a patient with dyspnea are essential. The brain can survive only a few minutes of anoxia. After 4 to 6 minutes without oxygen, brain cells may be severely and permanently damaged and may even die. Dead brain cells can never be replaced. Treatment of the patient will be ineffective if the airway is not patent and the patient is not breathing adequately.

Evaluation of the patient in respiratory distress includes observations, palpation, and auscultation. Use visual techniques at first sight of the patient—literally from the door as you are entering the room. Determine answers to the following questions when you assess a patient with respiratory distress:

- How is the patient positioned? Is the patient in a tripod position (elbows out)?
- Is the patient experiencing **orthopnea** (positional dyspnea)?
- Is there adequate rise and fall of the chest?
- Is the patient gasping?
- What is the color of the skin? Is the skin moist or clammy?

- Is there flaring of the nares present?
- Is the patient breathing through pursed lips?
- Do you note any **retractions** (skin pulling in around the ribs during inspiration):
 - Intercostal?
 - At the suprasternal notch?
 - At the supraclavicular fossa?
 - Subcostal?
- Is the patient using accessory muscles to breathe?
- Is the patient's chest wall moving symmetrically? (**Asymmetric chest wall movement**, when one side of the chest moves less than the other, indicates that airflow into one lung may be decreased.)
- Is the patient taking a series of quick breaths, followed by a prolonged exhalation phase?

A patient with inadequate breathing may appear to be working hard to breathe. This type of breathing pattern is called **labored breathing**. It requires effort and, especially among children, may involve the use of accessory muscles. Accessory muscles include the neck muscles (sternocleidomastoid), the chest pectoralis major muscles, and the abdominal muscles (**FIGURE 11-13**).

FIGURE 11-13 The accessory muscles of breathing are used when a patient is having difficulty breathing, but not during normal breathing. The accessory muscles include the sternocleidomastoid, pectoralis major, and abdominal muscles.

Street Smarts

The feeling of suffocating can be very frightening for a patient who is short of breath. Work quickly to provide appropriate oxygen therapy while coaching the patient's breathing. Many patients hyperventilate due to anxiety and the feeling that they cannot get enough air.

Accessory muscles are not used during normal breathing. Signs of inadequate breathing in adults are as follows:

- Respiratory rate of fewer than 12 breaths/min or more than 20 breaths/min in the presence of shortness of breath (dyspnea)
- Irregular rhythm, such as a patient taking a series of deep breaths followed by periods of **apnea** (absence of breathing)
- Diminished, absent, or noisy auscultated breath sounds
- Abdominal breathing
- Reduced flow of expired air at the nose and mouth
- Unequal or inadequate chest expansion, resulting in reduced tidal volume
- Increased effort of breathing—use of accessory muscles
- Shallow depth (reduced tidal volume)
- Skin that is pale, cyanotic (blue), cool, mottled or moist (clammy)
- Retractions
- Staccato speech patterns (one- to two-word dyspnea)

More information about recognizing labored breathing and respiratory distress in children is found in later chapters.

When you are assessing a patient with a potential airway compromise, pay particular attention to the external environment, such as high altitude, enclosed spaces, or potential poisonous gases. Remember personal safety if the environment is unsafe.

Next, auscultate breathing with and without a stethoscope. Is air movement noted at the mouth and nose? Can clear, equal, and bilateral breath sounds be heard over all lung fields?

Feel for air movement at the mouth and nose. Observe the chest for symmetry, and note any

paradoxical motion—the inward movement of the chest during inhalation and outward movement of the chest during exhalation, which is the opposite of normal chest wall movement during breathing and occurs on the side of injury (flail segment).

Evaluate for pulsus paradoxus, a condition in which the systolic blood pressure drops more than 10 mm Hg with inspiration. A change in pulse quality, or even the disappearance of a pulse, may also be detected. Pulsus paradoxus is generally seen in patients with decompensating COPD or severe pericardial tamponade. It may also indicate an increase in intrathoracic pressure (such as tension pneumothorax or a severe asthma attack).

A history of the present illness is a vital part of your assessment. Determine the evolution of this particular event:

- Was its onset sudden or gradual?
- Is there any known cause or trigger of the event?
- What was the duration (is the problem constant or recurrent)?
- Does anything alleviate or exacerbate the problem?
- Are there any other associated symptoms, such as a productive cough (if yes, what does the sputum look like?), chest pain or pressure, or fever?
- Were any interventions attempted before EMS arrival?
- Is the patient currently taking any medications? Is the patient compliant with the prescribed regimens?
- Is this a constant (chronic) or recurrent (episodic) problem?
- Has the patient been evaluated by a physician or admitted to the hospital for this condition in the past?
- Has the patient ever been intubated for this problem? If so, how does today's episode compare to that experience? This is one of the most important questions to ask; a condition bad enough to warrant intubation needs urgent attention to prevent a repeated occurrence.

Note protective reflexes of the airway, including coughing, sneezing, and gagging. A cough is a forceful, spastic exhalation that aids in clearing the bronchi and bronchioles. Sneezing clears the nasopharynx and is often caused by an irritant, such

TABLE 11-5 Respiratory Pattern Changes

Pattern	Characteristics
Cheyne-Stokes respirations	Rhythmic, gradually increasing rate and depth of respirations followed by gradual decrease of respirations with intermittent periods of apnea; associated with brain-stem injury
Kussmaul respirations	Deep, rapid respirations; common in patients with diabetic ketoacidosis
Biot (ataxic) respirations	Irregular pattern, rate, and depth of breathing with intermittent periods of apnea; results from increased intracranial pressure
Central neurogenic hyperventilation	Deep, rapid respirations similar to Kussmaul; also results from increased intracranial pressure
Apneustic respirations	Prolonged, gasping inhalation followed by extremely short, ineffective exhalation; associated with brainstem insult
Agonal gasps	Slow, shallow, irregular or occasional gasping breaths; results from brain anoxia. Agonal gasps may be seen when the heart has stopped but the brain continues to send signals to the muscles of respiration. This is not considered a form of respiration.

Data from: Fontanarosa PB, Christiansen S. Units of measure. Table 2: Selected laboratory tests, with reference ranges and conversion factors. In: American Medical Association, ed. *AMA Manual of Style: A Guide for Authors and Editors*. 10th ed. New York, NY: Oxford University Press; 2007:798-815.

as dust. The gag reflex is a spastic pharyngeal and esophageal reflex as a result of a stimulus of the posterior pharynx to prevent foreign objects from entering the trachea.

Sighing and hiccupping are other modified forms of respiration. Sighing is an involuntary deep breath that increases opening of the alveoli, preventing atelectasis. The average person sighs approximately once every 5 minutes. Hiccupping is a sudden inhalation, caused by spastic contraction of the diaphragm cut short by closure of the glottis. Persistent hiccupping may be clinically important.

Respiratory pattern changes indicate serious injury or illness. **TABLE 11-5** shows various respiratory patterns and causes. Irregular respiratory breathing patterns may be related to a specific condition. For example, Cheyne-Stokes respirations are often seen in patients with stroke and patients with serious head injuries (**FIGURE 11-14**).

Serious head injuries may also cause changes in the normal respiratory rate and pattern of breathing. The result may be irregular, ineffective respirations that may or may not have an identifiable pattern (**ataxic respirations**). Patients experiencing a metabolic or toxic disorder may display other irregular respiratory patterns such as Kussmaul respirations.

FIGURE 11-14 Cheyne-Stokes breathing shows irregular respirations followed by a period of apnea.

© Jones & Bartlett Learning.

You should be aware that a patient may appear to take a breath after the heart has stopped. During these occasional, **agonal gasps**, the patient is not breathing. In patients with agonal gasps, you will need to provide artificial ventilations and, very likely, chest compressions.

Whereas rapid breathing is a compensatory mechanism to help patients in respiratory distress, some patients are so ill that their body is not able to compensate for their respiratory distress. The patients may look like they are compensating; however, no clinical improvement will be noticeable. You need to be vigilant when monitoring patients in respiratory distress because their condition may decline rapidly.

Patients with inadequate breathing have inadequate minute volume and need to be treated immediately. This condition is most easily recognized in patients who are unable to speak in complete sentences when at rest or who have a fast or slow respiratory rate, either of which may result in a reduction in tidal volume. Emergency medical care includes airway management, supplemental oxygen, and ventilatory support.

Street Smarts

If more than one patient with similar symptoms requires treatment, consider the presence of toxic gases. For example, carbon monoxide may be present in a residence with improperly vented heating systems and may be poisoning the occupants. Fire departments generally carry carbon monoxide detectors, and even some EMS services carry handheld carbon monoxide detectors to aid in the process of assessing ambient air.

Assessment of Respiration

A patient's level of consciousness (LOC) and skin color are excellent indicators of respiration. During normal respiration, oxygen and carbon dioxide diffuse in and out of tissues and allow aerobic metabolism to take place. When you are assessing the brain and skin tissues, it will be apparent if the patient has adequate oxygen reaching these areas. A patient presenting with an altered LOC may not have adequate oxygen reaching the brain. This lack of oxygen can cause rapid changes in the patient's mental status. Therefore, when treating patients with an altered mental status, always consider the possibility that the patients may not be getting adequate oxygen to the brain and that you need to consider the possible underlying causes. However, remember to determine a baseline mental status on the patient. Some patients naturally have an abnormal mental status because of a previous medical condition. Ask family members what the patient's normal mental status is.

Just as an altered LOC indicates inadequate respiration, the same is true for patients with poor skin color. As oxygen fails to reach the skin from a lack of perfusion or poor oxygenation, the color of the skin changes to reflect the inadequate oxygen. Pale skin

and mucous membranes are typically associated with poor perfusion caused by illness or shock. As this condition worsens, cyanosis becomes noticeable first peripherally, in the fingertips, and then centrally, in the mucous membranes and around the lips. Eventually, if the poor perfusion or oxygenation is not corrected, anaerobic metabolism will take place. This could cause the skin to become marked with blotches of different colors, commonly referred to as mottling.

Whereas assessment of a patient's baseline mental status and color of the skin and mucous membranes provides good indicators of respiration, you should also consider proper oxygenation when assessing patients. Several methods can be used to assess proper oxygenation, including assessing skin color, mental status, and **pulse oximetry**.

Pulse Oximetry

Pulse oximetry is a simple, rapid, safe, and noninvasive method of measuring—minute by minute—how well a person's hemoglobin is saturated. Pulse oximetry is considered a routine vital sign and can be used as part of any patient assessment.

A pulse oximeter measures the percentage of hemoglobin in the arterial blood that is saturated with oxygen (**FIGURE 11-15**). Under normal circumstances, hemoglobin is saturated with oxygen. A sensor probe, clipped to the patient's finger or earlobe, uses a light-emitting diode to transmit light

FIGURE 11-15 Pulse oximetry is a noninvasive method of assessing arterial oxygen saturation.

© Jones & Bartlett Learning.

through the vascular bed to a light-sensing detector. The amount of light transmitted across the vascular bed depends on the proportion of hemoglobin that is saturated with oxygen. To ensure that the instrument is measuring arterial and not venous **oxygen saturation (SpO₂)**, pulse oximeters are designed to assess only pulsating blood vessels. Subsequently, pulse oximeters also measure the patient's pulse. One way to check the functioning of a pulse oximeter is to compare the pulse reading it provides with your own measurement of the patient's pulse by palpation.

A person with normal oxygenation and normal perfusion should have an SpO₂ level of greater than 95% while breathing room air. A reading of less than 95% in a nonsmoker suggests hypoxemia and a need for supplemental oxygen therapy.

Situations in which pulse oximeters may be useful in prehospital emergency medical care include the following:

- **Monitoring the oxygenation status of a patient during an attempt to insert an advanced airway or during suctioning.** The low-saturation alarm on the pulse oximeter can signal that you should abort the attempt and ventilate the patient.
- **Identifying deterioration in the condition of a trauma patient.** In a patient with multiple trauma, the signs of a developing tension pneumothorax may not be evident until the condition is advanced. A declining SpO₂ level can alert you to a problem and prompt a search for the cause of the problem.
- **Identifying deterioration in the condition of a patient with cardiac disease.** Pulse oximetry may enable early identification of patients who are experiencing heart failure in the wake of acute myocardial infarction.
- **Identifying high-risk patients with respiratory conditions.** For example, pulse oximetry may identify patients with asthma who are having serious attacks or patients with emphysema who are in severe decompensation.
- **Assessing vascular status in orthopaedic trauma.** Pulse oximetry is routine practice in assessing a fractured extremity to evaluate circulation distal to the fracture. Loss of a pulse means that the limb is in jeopardy and may require urgent action in the field if transport time is long. A pulse oximeter clipped to a

finger or toe on a broken limb might provide critical information about the ongoing circulation to the limb.

The usefulness of a pulse oximeter depends on its ability to provide accurate information. A pulse oximeter that gives a reading of 99% when the patient is severely hypoxemic will not provide helpful information and could result in inadequate or erroneous interventions. Be aware of circumstances that might produce erroneous readings:

- **Bright ambient light** may enter the spectrophotometer of the pulse oximeter and create an incorrect reading. Protect the sensor clip by covering it with a towel or aluminum foil.
- **Patient motion** can confuse the pulse oximeter because it may mistake motion for arterial pulsation and read the oxygen saturation level from a vein rather than an artery.
- **Poor perfusion** makes it difficult for the pulse oximeter to sense a pulse and therefore to generate a reading. Poor perfusion occurs in states such as shock, cardiac arrest, and cold exposure. If the vessels in a patient's limbs are constricted and the limbs are cold, then it may be necessary to place the pulse oximeter clip on the earlobe or nose.
- **Nail polish** will prevent the sensor from working properly. Carry disposable acetone (nail polish remover) swabs to quickly remove nail polish.
- **Venous pulsations** may occur in some patients with right-side heart failure as a result of the systemic backup of blood. If a vein is pulsating, then the pulse oximeter may regard it as an artery and measure venous oxygen saturation.
- **Abnormal hemoglobin** may produce a falsely normal SpO₂ level. Examples include situations such as anemia where there is a deficiency of hemoglobin, so even if the hemoglobin is fully saturated, there is still a lack of oxygen, and carbon monoxide poisoning where the hemoglobin is fully saturated, but with carbon monoxide instead of oxygen.

Remember, do not make treatment decisions based solely on pulse oximetry, and be aware of its limitations. In patients with substantial vasoconstriction or low perfusion states (including cardiac arrest), there may not be enough peripheral

Words of Wisdom

Remember that a pulse oximeter can detect only the saturation of hemoglobin. It cannot identify the gas that is saturating the hemoglobin. When carbon monoxide is present in the inspired gas, it displaces oxygen from the hemoglobin. Carbon monoxide, which has an affinity for hemoglobin that is 200 to 250 times greater than that of oxygen for hemoglobin, has similar characteristics in arterial blood. Therefore, the dual wavelengths of infrared light used by the pulse oximeter may not be able to distinguish between carbon monoxide and oxygen, producing a falsely high reading. In cases of carbon monoxide poisoning, the SpO_2 reading can be normal in the context of hypoxia.

It is essential to pay close attention to the scene size-up and to treat the patient instead of the diagnostic equipment. The pulse oximeter is designed to detect gross abnormalities, not subtle changes.

perfusion to be detected by the sensor. In these cases, move the sensor to a more central location (bridge of the nose or ear lobe). Always consult the manufacturer's guidelines for proper placement and troubleshooting of these devices.

Words of Wisdom

Patients who live at high altitudes may have a reading that is lower than normal due to the decreased partial pressure of oxygen, which is the driving force for gas exchange in the lungs. The actual percentage of oxygen in atmospheric air is still 21%—the same as it is at sea level. As altitude increases, the pressure exerted on oxygen molecules decreases (Boyle's law), so there is less pressure to assist in diffusion from the lungs into the bloodstream. When the intercostal muscles and the diaphragm contract, pressure inside the thorax decreases in relation to atmospheric pressure. Because atmospheric pressure is decreased at high altitudes, diffusion is decreased. Oxygen molecules can diffuse much more easily into the blood at sea level because atmospheric pressure is greater. The body adjusts (much like it does in patients who rely on hypoxic drive), or acclimates, to cope with the lack of oxygen at high altitudes. If changes are made quickly, or if the body does not acclimate, then the risk of developing altitude sickness greatly increases. For more on Boyle's law and problems at altitude, see Chapter 34, *Environmental Emergencies*.

Street Smarts

National Football League players with a history of sickle cell anemia are often not allowed to play in Mile High Stadium in Denver, Colorado, because of its high altitude of 5,280 feet (1,609 m). With the ability of the blood to carry oxygen already compromised, hypoxia can rapidly develop in these players. Familiarize yourself with not only the area in which you work, but also how the environment affects patients with various medical conditions.

The pulse oximeter is a valuable adjunct to aid in decision making, but it is not a replacement for a complete assessment. Because of many factors, the pulse oximeter may give falsely high or low readings. When you are conducting a complete patient assessment, consider using pulse oximetry readings as one additional measure to use while obtaining all other comprehensive information you need. Assess the patient for signs and symptoms of adequate oxygenation. If a patient has signs, such as cyanosis or pale or clammy skin, or symptoms, such as shortness of breath, and a normal SpO_2 reading, treat the patient's condition, not the diagnostic device.

Peak Expiratory Flow Measurement

In patients with certain reactive airway diseases (such as asthma), you can evaluate bronchoconstriction by measuring the peak rate of a forceful exhalation with a peak expiratory flowmeter (**FIGURE 11-16**). An increasing peak expiratory flow suggests that the patient is responding to treatment.

FIGURE 11-16 Peak expiratory flowmeters are used to quantify the degree of bronchoconstriction.

Courtesy of Rhonda Hunt.

(such as inhaled bronchodilators). A decreasing peak expiratory flow may be an early indication that the patient's condition is deteriorating.

Peak expiratory flow varies based on sex, height, and age. Healthy adults have a peak expiratory flow rate of 350 to 750 mL. To assess peak expiratory flow, place the patient in a seated position with legs dangling. Assemble the flowmeter, and ensure that it reads zero. Ask the patient to take a deep breath, place the mouthpiece in the mouth, and exhale as forcefully as possible (ensure no air leaks around the device or comes from the patient's nose). Perform the test three times, and take the best peak flow rate of the three readings.

Arterial Blood Gas Analysis

AEMTs are not typically trained to obtain arterial blood specimens and do not carry the equipment needed to analyze the patient's blood. As a result, you will rely on noninvasive methods of assessing ventilation and oxygenation (such as pulse oximetry and capnography/capnometry).

Analysis of arterial blood gases (ABGs) provides the most comprehensive quantitative information about the respiratory system. In this procedure, blood is obtained from a superficial artery, such as the radial or femoral artery. The blood is then analyzed for pH, Paco_2 , PaO_2 , HCO_3^- (concentration of bicarbonate ions), base excess (indicating acidosis or alkalosis), and Spo_2 levels. Normal ABG values are summarized in **TABLE 11-6**.

TABLE 11-6 Normal Arterial Blood Gas Values	
pH	7.35 to 7.45
PaO_2	80 to 100 mm Hg
Paco_2	35 to 45 mm Hg
HCO_3^-	21 to 28 mEq/L
Base (excess or deficit)	−2 to 3 mEq/L
SaO_2	>95%

Abbreviations: HCO_3^- , concentration of bicarbonate ions; Paco_2 , partial pressure of carbon dioxide; PaO_2 , partial pressure of oxygen; pH, potential of hydrogen; SaO_2 , oxygen saturation

Data from: Fontanarosa PB, Christiansen S. Units of measure. Table 2: selected laboratory tests, with reference ranges and conversion factors. In: American Medical Association, ed. *AMA Manual of Style: A Guide for Authors and Editors*. 10th ed. New York, NY: Oxford University Press; 2007:798-815.

With ABG measurements, the values of pH and HCO_3^- are used to evaluate the acid-base status of the patient. The Paco_2 value is an indicator of the effectiveness of ventilation. The values of PaO_2 and Spo_2 are indicators of oxygenation. To maintain normal ABG values, a balance between alveolar volume and perfusion of the alveolar capillaries must be maintained.

End-Tidal Carbon Dioxide Assessment

Carbon dioxide can be described as the “smoke of metabolism.” The body uses oxygen as its fuel and makes carbon dioxide as its by-product. As long as oxygen is delivered to the cells and tissues, the production of carbon dioxide continues. A helpful analogy is a motor vehicle engine. As long as gasoline continues to burn, exhaust is produced. In the human body, carbon dioxide is the exhaust.

An **end-tidal carbon dioxide (ETCO_2) monitor** detects the presence of carbon dioxide in exhaled air. These monitoring tools are important adjuncts for determining the adequacy of ventilations and proper placement of advanced airways. The types of ETCO_2 monitors include colorimetric, digital, and digital/waveform.

A **colorimetric carbon dioxide detector** provides qualitative information regarding the presence of carbon dioxide in the patient's exhaled breath; that is, it does not assign a numeric value. The colorimetric CO_2 detector is attached between any tube inserted into the trachea and the ventilation device. After six to eight positive-pressure breaths—the amount of time it takes for carbon dioxide to accumulate in the device—the specifically treated paper inside the detector should turn from purple to yellow during exhalation (**FIGURE 11-17**). Air exhaled through a tube that has been properly placed in the trachea of a patient with adequate perfusion should contain 4% to 5% carbon dioxide, which will cause the paper to turn yellow during exhalation. If the tube is in the esophagus, a negligible amount (less than 0.5%) of carbon dioxide will be present in the exhaled gas; this amount will cause the paper to remain purple during exhalation.

Several limitations exist with the colorimetric CO_2 detector. The device might give a false-positive reading if the patient has carbon dioxide trapped in the stomach from the ingestion of carbonated beverages. Furthermore, the device is sensitive to

FIGURE 11-17 The paper inside the colorimetric carbon dioxide detector should turn from purple to yellow during exhalation, indicating the presence of exhaled carbon dioxide.

Courtesy of Marianne Gausche-Hill, MD, FACEP, FAAP.

extremes of temperature and humidity; it may be less reliable if vomitus or other secretions get inside it; and the paper inside the device degrades over time, resulting in a less reliable reading.

A **capnometer** provides quantitative information, in real time, by displaying a numeric reading of exhaled carbon dioxide levels. It uses a special adapter, which attaches between the advanced airway device and ventilation device (**FIGURE 11-18**). Because it provides quantitative data, the capnometer is more reliable than the colorimetric CO₂ detector.

A **capnographer** is a device that provides a graphic representation of exhaled carbon dioxide levels. It performs the same function and attaches in the same way as the capnometer. The two types of capnographers are waveform and digital/waveform.

Waveform capnography provides quantitative, real-time information regarding the patient's exhaled carbon dioxide level. Unlike capnometry, however, waveform capnography displays a graphic waveform (**FIGURE 11-19**). In most cases, portable cardiac monitors/defibrillators provide a numeric reading and a waveform (also called digital/waveform capnography and quantitative waveform capnography).

Quantitative waveform capnography has many applications in emergency medicine, including the detection of bronchospasm, hypoventilation, and

FIGURE 11-18 A capnometer.

© Smiths Medical.

FIGURE 11-19 A normal capnographic waveform.

© Jones & Bartlett Learning.

hyperventilation. Quantitative waveform capnography is the recommended method of monitoring initial and ongoing placement of an advanced airway device. Capnography can also serve as an indicator of the effectiveness of chest compressions and to detect return of spontaneous circulation (ROSC). The provision of this information is possible because blood must circulate through the lungs for carbon dioxide to be exhaled and measured. When ROSC occurs, you would expect a large amount of carbon dioxide to be returned to the lungs. Waveform capnography can be monitored in spontaneously breathing patients with an adequate airway by applying a special nasal cannula device to the patient and connecting the sampling line to

FIGURE 11-20 FilterLine nasal cannula device for monitoring end-tidal carbon dioxide in a spontaneously breathing patient.

the cardiac monitor/defibrillator (**FIGURE 11-20**). If the patient has an advanced airway, then place an in-line adapter between the advanced airway device and ventilation device and connect the sampling line to the cardiac monitor/defibrillator (**FIGURE 11-21**).

Because carbon dioxide rapidly equilibrates in the alveolar gases, the carbon dioxide concentration in exhaled gases—particularly the gases present near the end of exhalation—can be used to grossly approximate arterial P_{aCO_2} levels, which normally range between 35 and 45 mm Hg. Typically, $ETCO_2$ level is approximately 2 to 5 mm Hg lower than the arterial P_{aCO_2} level, but this amount varies depending on the volume of alveolar dead space and any $\dot{V}/\dot{Q}$ mismatch present. Because carbon dioxide is present only in negligible (0.5% or less) concentrations in the esophagus, use of an $ETCO_2$ detector (specifically, quantitative waveform capnography) is a reliable, and essential, method for confirming and monitoring advanced airway placement.

Use of $ETCO_2$ monitoring is limited with patients in cardiac arrest. In a patient with a short arrest interval, exhaled carbon dioxide may be detected despite a lack of perfusion. Patients with prolonged cardiac arrest, however, will have minimal levels of

FIGURE 11-21 FilterLine in-line end-tidal carbon dioxide device for use in the patient with an advanced airway.

exhaled carbon dioxide because of severe acidosis and minimal carbon dioxide return to the lungs.

Opening the Airway

Emergency medical care begins with ensuring an open airway. If you cannot immediately open and maintain an airway, you cannot provide effective patient care.

When you respond to a call and find an unresponsive patient, you need to assess and determine immediately whether the patient has an open airway and breathing is adequate and if the patient has a pulse. The patient needs to be in the supine position to adequately open the airway and assess breathing. A patient found in the prone position must be properly positioned to allow for assessment of airway and breathing and to begin cardiopulmonary resuscitation (CPR) should it be necessary. Currently, health care workers are taught to begin CPR with high-quality compressions if cardiac arrest is suspected. The patient should be log rolled as a unit so the head, neck, and spine all move together without twisting. To position an unresponsive patient to open the airway, follow the steps in

SKILL DRILL 11-1.

Skill Drill 11-1 Positioning an Unresponsive Patient

Step 1

Kneel beside the patient. Kneel far enough away so that the patient, when rolled toward you, does not come to rest in your lap. Place your hands behind the back of the patient's head and neck to provide in-line stabilization of the cervical spine as your partner straightens the patient's legs.

Step 2

Have your partner place their hands on the patient's far shoulder and hip.

Step 3

As you call the count to control movement, have your partner turn the patient toward you by pulling on the far shoulder and hip. Control the head and neck so that they move as a unit with the rest of the torso. In this way, the head and neck stay in the same vertical plane as the back. This single motion will minimize aggravation of any spinal injury. Replace the patient's farther arm back at their side.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Step 4

After the patient is positioned, maintain an open airway and assess the patient's airway and breathing status.

In an unresponsive patient, the most common airway obstruction is the patient's tongue, which falls back into the throat when the muscles of the throat and tongue relax (**FIGURE 11-22**). Dentures (false teeth), blood, vomitus, mucus, food, and other foreign objects may also create a blockage. Therefore, you should always be prepared to help clear and maintain a patent airway.

Head Tilt–Chin Lift Maneuver

Opening the airway to relieve an obstruction can often be done quickly and easily by simply tilting the patient's head back and lifting the chin in what is known as the **head tilt–chin lift maneuver**. For patients who have not sustained trauma, this simple maneuver is sometimes all that is needed for the patient to resume breathing.

FIGURE 11-22 The most common airway obstruction is the patient's tongue, which falls back into the throat when the muscles of the throat and tongue relax.

© Jones & Bartlett Learning.

FIGURE 11-23 The head tilt–chin lift maneuver is a simple technique for opening the airway in a patient without a suspected cervical spine injury.

© Jones & Bartlett Learning.

To perform the head tilt–chin lift maneuver, follow these steps (**FIGURE 11-23**):

1. With the patient in a supine position, position yourself beside the patient's head.
2. Place the heel of one hand on the patient's forehead, and apply firm backward pressure with your palm to tilt the patient's head back. This extension of the neck will move the tongue forward, away from the back of the throat, and clear the airway if the tongue is blocking it.

3. Place the fingertips of your other hand under the patient's chin. Do not compress the soft tissue under the chin because this may block the airway.
4. Lift the chin upward, bringing the entire lower jaw with it, helping to tilt the head back. Lift so that the teeth are nearly brought together, but avoid closing the mouth completely. Continue to hold the forehead to maintain the backward tilt of the head.

Special Populations

Patients with a history of rheumatoid arthritis or Down syndrome are predisposed to instability of the cervical spine, specifically at the first and second cervical vertebrae. The head tilt–chin lift maneuver should be avoided on these patients. Excessive force or hyperextension of the neck can cause partial dislocation of the cervical spine, which can potentially lead to paralysis. It is often better to open the airway of these patients using a jaw-thrust maneuver.

Jaw-Thrust Maneuver

The head tilt–chin lift maneuver will open the airway in most patients; however, if you suspect a cervical spine injury, use the jaw-thrust maneuver. The **jaw-thrust maneuver** is a technique to open the airway by placing the fingers behind the angle of the jaw and lifting the jaw upward. The jaw is displaced forward at the mandibular angle. You can easily seal a mask around the mouth while performing the jaw-thrust maneuver. This is the method of choice for patients with suspected cervical spine injury. Perform the jaw-thrust maneuver on an adult in the following manner (**FIGURE 11-24**):

1. Kneel above the patient's head. Place your fingers behind the angles of the lower jaw, and move the jaw upward. Use your thumbs to help position the lower jaw to allow breathing through the mouth and nose.
2. The completed maneuver should open the airway with the mouth slightly open and the jaw jutting forward.

A

B

FIGURE 11-24 Performing the jaw-thrust maneuver.

B. The completed maneuver should look like this.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

After the airway has been opened, the patient may start to breathe on their own. Assess whether breathing has returned.

With complete airway obstruction, there will be no movement of air. However, you may see the chest and abdomen rise and fall considerably with the patient's frantic attempts to breathe. Therefore, the presence of chest wall movement alone does not indicate breathing is present. Regular chest wall movement indicates that respiratory effort is present. Observing chest and abdominal movement is often difficult with a fully clothed patient. You may see little, if any, chest movement, even with normal breathing. This is particularly true in some patients with chronic lung disease. If you are

FIGURE 11-25 The tongue-jaw lift maneuver.

© Jones & Bartlett Learning.

not sure if the patient is moving enough air, begin ventilations.

Tongue-Jaw Lift Maneuver

The **tongue-jaw lift maneuver** is used more frequently to open a patient's airway to facilitate oropharyngeal suctioning. It cannot be used to ventilate a patient because it will not allow for an adequate mask seal on the patient's face. To perform the tongue-jaw lift maneuver, follow these steps (**FIGURE 11-25**):

1. Position yourself at the patient's side.
2. Place the hand closest to the patient's head on the forehead.
3. With your other hand, reach into the patient's mouth and hook your first knuckle under the incisors or gumline. While holding the patient's head and maintaining the hand on the forehead, lift the jaw straight up.

Special Populations

Routine procedures for patients with obesity can become extremely complicated. Airway procedures are made more difficult by a larger tongue, larger patient head size, and limited neck mobility associated with obesity. Bag-mask ventilation may be ineffective with patients in a supine position. Multiple studies have demonstrated that ramped positioning of the patient with obesity has a positive effect on the chances of successful airway management.^{1–6}

Ramping of the patient with obesity may be accomplished by utilizing pillows and/or blankets to achieve the desired position or with commercially manufactured ramping devices (**FIGURE 11-26**). Both methods carry equivalent rates of success and complication.^{1–6}

FIGURE 11-26 The ramped position with the head and shoulders elevated approximately 25° to 30° increases the chance of successful airway management. It is important to confirm that the external auditory meatus is in line with the sternal notch.

Data from Miller RD, Cohen NH, Eriksson LJ, et al. Chapter 55: Airway Management in the Adult. In: *Miller's Anesthesia*. 8th ed. Philadelphia, PA: Elsevier; 2015:1666.

Maintaining the Airway

After you have evaluated the airway, if the patient is breathing without assistance with a normal rate and adequate tidal volume (depth of breathing) and does not have a traumatic injury, place the patient in the **recovery position** to help maintain a clear airway (**FIGURE 11-27**). Take the following steps to put the patient in the recovery position:

1. Roll the patient onto the side so that the head, shoulders, and torso move at the same time without twisting.
2. Place the patient's lower arm and upper hand under their cheek.

FIGURE 11-27 In the recovery position, the patient is rolled onto the left or right side.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

After patients have resumed spontaneous breathing after being resuscitated, the recovery position will prevent the aspiration of vomitus. However, this position is not appropriate for patients with suspected spinal, hip, or pelvic injuries; nor is it adequate for patients who are unresponsive and require ventilatory assistance. Reposition such patients to provide access to the airway.

Suctioning

You must keep the airway clear so that you can ventilate the patient properly. If the airway is not clear, you will force material into the lungs and possibly cause a complete airway obstruction. Therefore, suctioning is your first priority. If you have any doubt about the situation, remember this rule: If you hear gurgling, the patient needs suctioning!

Suctioning Equipment

Portable, hand-operated, battery-operated, and fixed (mounted) types of suctioning equipment are essential for resuscitation (**FIGURE 11-28**). A portable suctioning unit must provide enough vacuum pressure and flow to allow you to suction the mouth and oropharynx effectively. Hand-operated suctioning units with disposable chambers are reliable, effective, and relatively inexpensive. A fixed suctioning unit should generate an airflow of more than 40 L/min and a vacuum of more than 300 mm Hg when the tubing is clamped.

A portable and fixed suctioning unit should be fitted with the following:

- Wide-bore, thick-walled, nonkinking tubing
- Soft and rigid suction catheters
- A nonbreakable, disposable collection bottle
- A supply of water for rinsing the tips

A

A **suction catheter** is a hollow, cylindrical device that is used to remove fluids and secretions from the airway. A **tonsil-tip catheter** is the best kind of catheter for suctioning the pharynx in adults and the preferred method for infants and children. These plastic tips have a large diameter and are rigid, so they do not collapse (**FIGURE 11-29**).

FIGURE 11-29 Tonsil-tip catheters are the best for suctioning the oropharynx because they have wide-diameter tips and are rigid.

© Jones & Bartlett Learning.

FIGURE 11-30 French, or whistle-tip, catheters are used in situations in which rigid catheters cannot be used, such as with a patient who has a stoma, patients whose teeth are clenched, or if suctioning the nose is necessary.

© Jones & Bartlett Learning.

Tips with a curved contour allow easy, rapid placement in the oropharynx. Soft plastic, nonrigid catheters, sometimes called French or whistle-tip catheters, are used to suction the nose and liquid secretions in the back of the mouth and in situations in which you cannot use a rigid catheter, such as for a patient with a **stoma** (**FIGURE 11-30**). A stoma is an opening through the skin that goes into an organ or other structure. For example, a rigid catheter could break off a patient's tooth, whereas a flexible catheter may be inserted along the cheeks without injury.

Before you insert any catheter, make sure to measure for the proper size. Use the same technique as you would use when measuring for an

oropharyngeal airway. You should use extreme caution when suctioning a responsive patient. Put the tip in only as far as you can visualize. Never insert a catheter past the base of the tongue because this action may result in gagging and vomiting and increases the possibility of aspiration.

Techniques of Suctioning

Inspect your suctioning equipment regularly to make sure it is in proper working condition. Turn on the suction, clamp the tubing, and make sure that the unit generates a vacuum of more than 300 mm Hg. Check that a battery-powered unit has charged batteries. Ensure that your suctioning equipment is at the patient's head and is easily accessible. Follow these steps to operate the suction unit:

1. Check the unit for proper assembly of all its parts.
2. Turn on the suctioning unit, and test it to ensure a vacuum pressure of more than 300 mm Hg.
3. Select and attach the appropriate catheter to the tubing.

Limit suctioning time to no more than 15 seconds at one time for adult patients, 10 seconds for children, and 5 seconds for infants. Suctioning removes oxygen from the airway along with obstructive material. Rinse the catheter and tubing with water to prevent clogging of the tube with dried vomitus or other secretions. Repeat suctioning only after the patient has been ventilated and reoxygenated.

Words of Wisdom

Suctioning time limits:

Adult: 15 seconds

Child: 10 seconds

Infant: 5 seconds

Pediatric patients are very susceptible to vagal stimuli and their heart rate will decrease if suctioning or stimulating the back of the throat occurs for too long.

To properly suction a patient's airway, follow the steps in **SKILL DRILL 11-2**.

At times, a patient may have secretions or vomitus that cannot be suctioned quickly and easily. Some suction units cannot effectively remove solid objects such as teeth, foreign bodies, and food. In these situations, remove the catheter from the patient's mouth, log roll the patient onto the side, and then clear the mouth carefully with your gloved finger. Only attempt to remove an object if it is visible during examination of the open mouth; blind sweeps of the back of the oropharynx may push an object farther down in the airway, making the obstruction worse. Copious frothy secretions may be produced as quickly as you can suction them from the airway. In this situation, you should suction the patient's airway for 15 seconds (less time in infants and children), then ventilate the patient for 2 minutes. This alternating pattern of suctioning and ventilating should continue until all secretions have been cleared from the patient's airway. Continuous ventilation is not appropriate if vomitus or other particles are present in the airway.

Clean and decontaminate your suctioning equipment after each use according to the manufacturer's guidelines. Place all disposable suctioning equipment (such as catheter and suction tubing) in a biohazard bag.

Tracheobronchial Suctioning of an Intubated Patient

Endotracheal (ET) intubation is a paramedic skill in which an ET tube is passed through the glottic opening to manage the airway when other less invasive methods are not sufficient. Following ET intubation, thick pulmonary secretions or other fluids may occlude the ET tube, preventing effective ventilation. You may at times assist with tracheobronchial suctioning of an intubated patient.

In such cases, you must pass a suction catheter into the ET tube to remove the secretions. Use sterile technique if possible; do not reinsert a catheter that is not sterile. Monitor the patient's oxygen saturation level during the procedure. **Preoxygenation** is essential before tracheobronchial suctioning. Lubricate a soft-tip (whistle-tip) catheter, and hyperoxygenate for 30 seconds to 1 minute. It may be necessary to inject 3 to 5 mL of sterile water down the ET tube to loosen secretions. Gently insert the

Skill Drill 11-2 Suctioning a Patient's Airway

Step 1

Make sure the suctioning unit is properly assembled, and turn on the suction unit. Test the suction by clamping the tubing and making sure the unit generates a vacuum of more than 300 mm Hg.

Step 2

Measure the catheter from the corner of the patient's mouth to the tip of the earlobe or angle of the jaw.

Step 3

Before applying suction, turn the patient's head to the side (unless you suspect cervical spine injury). Open the patient's mouth by using the cross-finger technique or tongue-jaw lift, and insert the catheter to the depth measured, without using force. Do not suction while inserting the catheter.

Step 4

Insert the catheter to the premeasured depth, and apply suction in a circular motion as you withdraw the catheter. Remember that you are removing oxygen while suctioning, so limit suctioning time to no more than 15 seconds in an adult, 10 seconds in a child, and 5 seconds in an infant.

FIGURE 11-31 Tracheobronchial suctioning involves passing a suction catheter into an ET tube to remove secretions.

© Jones & Bartlett Learning.

catheter until you feel resistance (**FIGURE 11-31**). Apply suction as the catheter is extracted, taking care not to exceed 15 seconds in an adult patient. Continue to ventilate and oxygenate the patient.

Basic Airway Adjuncts

The primary function of an airway adjunct is to prevent obstruction of the upper airway by the tongue and allow the passage of air and oxygen to the lungs.

Oropharyngeal Airway

An **oropharyngeal (oral) airway** is a hard, plastic airway designed to prevent the tongue from obstructing the glottis (**FIGURE 11-32**). This type of airway device is often used in conjunction with bag-mask ventilation.

Indications for the oral airway include the following:

- Unresponsive patients without a gag reflex (breathing or apneic)
- Any patient being ventilated with a bag-mask device who does not have a gag reflex

Contraindications for the oral airway include the following:

- Responsive patients
- Any patient (responsive or unresponsive) who has an intact gag reflex

An oropharyngeal airway should be inserted promptly in unresponsive patients who have no gag reflex. The patients may or may not be breathing on their own. The **gag reflex** is a protective reflex

FIGURE 11-32 An oral airway is used for unresponsive patients who have no gag reflex. It works to keep the tongue from blocking the airway.

© Jones & Bartlett Learning.

mechanism that prevents food and other particles from entering the airway. Inserting an oral airway in a patient with a gag reflex may result in vomiting or a spasm of the vocal cords. An oral airway is a safe, effective way to help maintain the airway of a patient with a possible spinal injury.

Special Populations

In children, the only acceptable method of inserting an oral airway is to use a tongue blade to hold the tongue down while inserting the airway straight in. Because the airways of children are undeveloped, rotating an oropharyngeal airway in the posterior pharynx may cause damage to the uvula and soft palate.

You must clearly understand when and how this device is used. If the oropharyngeal airway is not the proper size or is inserted incorrectly, it could actually push the tongue back into the pharynx, blocking the airway. Conversely, an oral airway that is too small could block the airway directly, just like any foreign body obstruction. Follow the steps in **SKILL DRILL 11-3** to insert an oropharyngeal airway.

Take care to avoid injuring the hard palate as you insert the airway. Roughness in your technique can cause bleeding that may aggravate airway problems or even cause vomiting.

If you encounter difficulty while inserting the oral airway, an alternative method may be used—inserting the oral airway with a 90° rotation. To do so, follow the steps in **SKILL DRILL 11-4**.

In some cases, a patient may become responsive and regain a gag reflex after you have inserted an oral airway. If this occurs, gently remove the

Skill Drill 11-3 Inserting an Oral Airway Into an Adult

Step 1

To select the proper size, measure the distance from the patient's earlobe to the corner of the mouth. Another acceptable method is to measure from the center of the mouth to the angle of the jaw.

Step 2

Open the patient's mouth with the cross-finger technique. Hold the airway upside down with your other hand. Insert the airway with the tip facing the roof of the mouth and slide it in until it touches the roof of the mouth.

Step 3

Rotate the airway 180° after it passes the soft palate. When inserted properly, the airway device will rest in the mouth with the curvature of the airway device following the contour of the anatomy. The flange should rest against the patient's lips or teeth. In this position, the airway will hold the tongue forward.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Skill Drill 11-4 Inserting an Oral Airway With a 90° Rotation

Step 1

Use a tongue depressor or bite stick to depress the tongue, ensuring the tongue remains forward.

Step 2

Insert the oral airway sideways from the corner of the mouth, until the flange reaches the teeth.

Step 3

Rotate the oral airway 90°, removing the depressor or bite stick as you exert gentle backward pressure on the oral airway until it rests securely in place against the lips and teeth.

© Jones & Bartlett Learning.

airway by pulling it out, following the normal curvature of the mouth and throat. Be prepared for the patient to vomit. Have suction available, and log roll the patient onto the side to allow any fluids to drain out.

Nasopharyngeal Airway

A **nasopharyngeal (nasal) airway** is soft rubber with a beveled tip and usually is used in a patient who has an intact gag reflex and is not able to maintain an airway (**FIGURE 11-33**). Patients with altered mental status or patients who have just had a seizure may also benefit from this type of airway. If a patient has sustained severe trauma to the head or face, consult medical control before inserting a nasopharyngeal airway. Use extreme care with such trauma patients. Although rare, if the airway is accidentally pushed through the hole caused by a basilar skull fracture, it may penetrate through the cranium and into the brain.

This type of airway is usually better tolerated by patients who have an intact gag reflex. It is not as likely as the oropharyngeal airway to cause vomiting. The distal tip of the nasopharyngeal airway rests in the hypopharynx behind the tongue. You should

FIGURE 11-33 A nasal airway is better tolerated by patients who have an intact gag reflex.

© Jones & Bartlett Learning.

coat the airway well with a water-soluble lubricant (eg, KY, Lubifax, Surgilube) before it is inserted. Be aware that slight bleeding may occur even when the airway is inserted properly. However, you should never force the airway into place. If you meet resistance, then try to pass the airway device down the other nostril.

Indications for the nasopharyngeal airway include the following:

- Patients with an altered mental status who still have an intact gag reflex
- Patients who otherwise will not tolerate an oropharyngeal airway

YOU are the Provider

Part 3

Your partner indicates that he is having difficulty maintaining an effective mask seal because of the patient's dentition, and you notice that the pulse oximetry reading is not increasing. On the basis of these findings and the seriousness of the patient's condition, you decide that he is a candidate for insertion of the King LT airway. You quickly remove the King LT (size 5) from your airway bag and check the patency of the balloons by inflating them with the recommended 80 mL of air. Finding no leakage, you position the patient's head and gently insert the airway until the base of the connector is aligned with the gums. After the King LT airway has been inserted, you quickly fill the balloon with 80 mL of air and direct your partner to resume ventilations while you assess for breath sounds.

Recording Time: 8 Minutes

Respirations	12 breaths/min; clear
Pulse	120 beats/min; regular
Skin	Clammy, cyanotic
Blood pressure	90/42 mm Hg
Oxygen saturation (SpO₂)	82% and increasing with 15 L/min
Pupils	Pupils Equal, Round, and Reactive to Light and Accommodation (PERRLA)

5. What are the indications for insertion of an advanced airway?
6. What are the contraindications for insertion of a King LT airway?

Contraindications for the nasopharyngeal airway include the following:

- Severe head injury with blood draining from the nose (epistaxis)
- Potential for basilar skull fracture

- History of fractured nasal bone
- Meeting with resistance during insertion (ie, deviated septum; try other nare)

Follow the steps in **SKILL DRILL 11-5** to ensure correct placement of the nasopharyngeal airway.

Skill Drill 11-5 Inserting a Nasal Airway

Step 1

Before inserting the airway device, be sure you have selected the proper size. Measure the distance from the tip of the patient's nose to the earlobe or the angle of the jaw. The diameter should be roughly equal to the diameter of the patient's little finger. If the nasopharyngeal airway is too long, it will obstruct the patient's airway. Coat the tip with a water-soluble lubricant.

Step 2

In almost all patients, one nostril is slightly larger than the other. Insert the lubricated airway device into the larger nostril with the curvature following the floor of the nose. If using the right nare, the bevel should face the septum. If using the left nare, insert the airway device with the tip of the airway pointing upward, which will allow the bevel to face the septum.

Step 3

Gently advance the airway. If using the left nare, insert the nasopharyngeal airway until you feel resistance. Then rotate the nasopharyngeal airway 180° into position. This rotation is not required if using the right nare.

Step 4

Continue until the flange rests against the skin. If you feel any resistance or obstruction, remove the nasal airway and insert it into the other nostril. When completely inserted, the flange rests against the nostril. The other end of the airway opens into the posterior pharynx. If the patient becomes intolerant of the nasal airway, you may have to remove it. Precautions similar to those used when removing an oral airway should be followed.

Supplemental Oxygen

You should administer supplemental oxygen to any patient with potential hypoxia, even if the patient's clinical appearance is otherwise normal. By enriching atmospheric air with supplemental oxygen, you subsequently increase oxygen to the cells, thereby reducing pain and further damage; for example, to myocardial tissue. Increasing the available oxygen also enhances the body's compensatory mechanisms during shock and other distressed states. The oxygen delivery method must be reassessed frequently and adjusted accordingly based on the patient's clinical condition and breathing adequacy.

Historically, oxygen was administered to patients whose clinical condition did not otherwise indicate its use (that is, no evidence of respiratory compromise, with an oxygen saturation level greater than 94%). Limited evidence suggests that supplemental oxygen in a well-oxygenated patient may not be in the patient's best interest, because issues such as oxidative stress and hyperoxic injury are of concern. However, the evidence that oxygen is helpful to a patient with hypoxia is profound, so if you are in doubt as to the patient's oxygenation status, then administer supplemental oxygen.^{7,8}

Current guidelines from the American Heart Association for patients with chest pain or evidence of acute coronary syndromes state that if the patient is not experiencing respiratory distress and has an oxygen saturation level that is greater than or equal to 94%, then supplemental oxygen is not indicated.⁹ Follow your local protocols regarding supplemental oxygen administration.

Some tissues and organs need a constant supply of oxygen to function normally. *Never withhold oxygen from any patient who might benefit from it, especially if you must assist ventilations.*

Supplemental Oxygen Equipment

In addition to knowing when and how to give supplemental oxygen, you must understand how oxygen is stored and the various hazards associated with its use.

Oxygen Cylinders

The oxygen that you will give to patients is usually supplied as a compressed gas in green, seamless steel or aluminum cylinders. Some cylinders may

FIGURE 11-34 Oxygen tanks for medical use have a series of letters and numbers stamped into the metal on the collar of the cylinder.

© Jones & Bartlett Learning.

be silver or chrome with a green area around the valve stem on top. Newer cylinders are often made of lightweight aluminum or spun steel; older cylinders are much heavier.

Check to make sure that the cylinder is labeled for medical oxygen. You should look for letters and numbers stamped into the metal on the collar of the cylinder (**FIGURE 11-34**). The month and year stamps, which indicate when the cylinder was last tested, are particularly important. Generally, aluminum cylinders are tested every 5 years; composite cylinders are tested every 3 years.

Oxygen cylinders are available in several sizes. The two sizes that you will most often use are the D (or jumbo D) cylinder, which contains 350 L, and the M cylinder, which contains 3,000 L (**FIGURE 11-35**). The D (or jumbo D) cylinder can be carried from your unit to the patient. The M tank remains on board your unit as a main supply tank. Other sizes that you will see are A, E, G, H, and K (**TABLE 11-7**). Another naming system for identifying the size of the oxygen cylinder has been introduced. Per this naming convention, cylinders are labeled with M (for medical), followed by a number.

The length of time you can use an oxygen cylinder depends on the pressure in the cylinder and the flow rate. A method of calculating cylinder duration, or tank life, is shown in **TABLE 11-8**.

Liquid Oxygen

Liquid oxygen is oxygen that is cooled to its aqueous state. It converts to the gaseous state when warmed.

FIGURE 11-35 The cylinders most commonly found on an ambulance are the D (or jumbo D) and M size cylinders.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

Liquid oxygen is becoming more commonly used as an alternative to compressed gas oxygen. There are advantages and disadvantages of liquid oxygen. A much larger volume of gaseous oxygen can be stored in the liquid state, and containers do not need to be filled as often. Liquid oxygen units also weigh less than aluminum or steel tanks. For these reasons, many people who receive long-term oxygen therapy use liquid oxygen units. Unfortunately, units for liquid oxygen generally require upright storage and have special requirements for filling, large-volume storage, and cylinder transfer.

TABLE 11-7 Oxygen Cylinder Sizes Carried on the Ambulance

Size	Volume, Liters
D	350
Jumbo D	500
E	625
M	3,000
G	5,300
H, A, K	6,900

TABLE 11-8 Oxygen Cylinders: Duration of Flow

Formula:

$$\frac{(\text{Tank pressure in psi} - 200 \text{ psi [the safe residual pressure]}) \times \text{Cylinder constant}}{\text{Flow rate in L/min}} = \text{Duration of flow in minutes}$$

Cylinder constant for a given cylinder size:

A = 3.14	G = 2.41
D = 0.16	H = 3.14
E = 0.28	K = 3.14
M = 1.56	

Steps:

Determine the life of an M cylinder that has a pressure of 2,000 psi and a flow rate of 10 L/min.

$$\frac{(2,000 - 200) \times 1.56}{10} = \frac{2,808}{10} = 281 \text{ min, or } 4 \text{ h } 41 \text{ min}$$

Abbreviation: psi, pounds per square inch

© Jones & Bartlett Learning.

Safety Considerations

Compressed gas cylinders must be handled very carefully because their contents are under pressure. Cylinders are fitted with pressure regulators to make sure that patients receive the right amount and type of gas. Make sure that the correct pressure regulator is firmly attached before you transport the cylinders. A puncture or hole in the tank can cause the cylinder to become a deadly missile. Do not handle a cylinder by the neck assembly alone. Cylinders should be secured with mounting brackets when they are stored on the ambulance. Oxygen cylinders that are in use during transport should be positioned and secured to prevent the tank from falling and to protect the valve-gauge assembly from damage. Contact with the liquid oxygen should be prevented at all costs. Severe tissue damage, including frostbite and tissue necrosis from frostbite, can occur.

Pin-Indexing System

The compressed gas industry has established a **pin-indexing system** for portable cylinders to prevent an oxygen regulator from being connected to a carbon dioxide cylinder, and so on. When preparing to administer oxygen, always check to be sure that the pinholes on the cylinder exactly match the corresponding pins on the regulator.

The pin-indexing system features a series of pins on a yoke that must be matched with the holes on the valve stem of the gas cylinder. The arrangement of the pins and holes varies for different gases according to accepted national standards (**FIGURE 11-36**). Other gases that are supplied in portable cylinders, such as acetylene, carbon dioxide, and nitrogen, use regulators and flowmeters that are similar to those used with oxygen cylinders. Each cylinder of a specific gas has a given pattern and a given number of pins. These safety measures make it impossible for you to attach a cylinder of nitrous oxide to an oxygen regulator. The oxygen regulator will not fit.

The outlet valves on E size or smaller cylinders are designed to accept yoke-type pressure-reducing gauges, which conform to the pin-indexing system (**FIGURE 11-37**).

The safety system for large cylinders is known as the **American Standard System**. In this system, cylinders larger than E size are equipped with threaded gas outlet valves. The inside and outside

FIGURE 11-36 The locations of the pin-indexing safety system holes in a cylinder valve face. Each cylinder of a specific gas has a given pattern and a given number of pins.

© Jones & Bartlett Learning.

FIGURE 11-37 A yoke-type pressure-reducing gauge is used with a portable oxygen cylinder.

© dream designs/Shutterstock.

thread sizes of these outlets vary depending on the gas in the cylinder. The cylinder will not accept a regulator valve unless it is properly threaded to fit that regulator. The purpose of these safety devices is the same as in the pin-indexing system: to prevent the accidental attachment of a regulator to a wrong cylinder.

Pressure Regulators

The pressure of gas in a full oxygen cylinder is approximately 2,000 psi. This is far too much pressure to be safe or useful for your purposes. Regulators reduce the pressure to a more useful range, usually 40 to 70 psi. Most pressure regulators that are currently in use reduce the pressure in a single stage, although multistage regulators exist. A two-stage regulator will reduce the pressure first to 700 psi and then to 40 to 70 psi.

After the pressure is reduced to a workable level, the final attachment for delivering the gas to the patient is usually one of the following:

- A quick-connect female fitting that will accept a quick-connect male plug from a pressure hose or ventilator or resuscitator
- A flowmeter that will permit the regulated release of gas measured in liters per minute

Safety

Slowly open the oxygen tank after attaching the regulator, and check for leaks. Remember that although oxygen itself is not combustible, it supports combustion, and any ignition source may cause a fire or an explosion in an oxygen-rich environment—especially if oxygen is being released too quickly from the cylinder at the time or if the seal between the regulator and oxygen cylinder is not secure.

Flowmeters

Flowmeters are usually permanently attached to pressure regulators on emergency medical equipment. The two types of flowmeters that are commonly used are pressure-compensated flowmeters and Bourdon-gauge flowmeters.

A pressure-compensated flowmeter incorporates a float ball within a tapered, calibrated tube. The float rises or falls according to the gas flow within the tube. The flow of gas is controlled by a needle valve located downstream from the float ball. This type of flowmeter is affected by gravity and must always be maintained in an upright position for an accurate flow reading (**FIGURE 11-38**).

By contrast, the **Bourdon-gauge flowmeter** is not affected by gravity and can be placed in any position. This pressure gauge is calibrated to record the

FIGURE 11-38 Pressure-compensated flowmeters contain a float ball that rises or falls according to the gas flow within the tube. It must be maintained in an upright position for an accurate reading.

FIGURE 11-39 The Bourdon-gauge flowmeter is not affected by gravity and can be placed in any position.

© American Academy of Orthopaedic Surgeons.

flow rate (**FIGURE 11-39**). The major disadvantage of this type of flowmeter is that it does not compensate for backpressure.

As a result, it will usually record a higher flow rate when there is any obstruction to gas flow downstream.

Operating Procedures

To place an oxygen cylinder into service, follow the steps in **SKILL DRILL 11-6**.

Open the flowmeter to the desired flow rate. Flow rates will vary based on the oxygen-delivery device being used. Remember that you must be completely familiar with the equipment before attempting to use it on a patient. After the oxygen is flowing at the desired rate, confirm flow from the device, then apply the oxygen device to the patient and make any necessary adjustments. Monitor the patient's reaction to the oxygen and to the oxygen device, and periodically recheck the regulator

gauge to make sure there is sufficient oxygen in the cylinder. Disconnect the tubing from the flowmeter nipple and turn off the cylinder valve when oxygen therapy is complete or when the patient has been transferred to the hospital and is using the hospital's oxygen system. In a few seconds, the sound of oxygen flowing from the nipple will cease. This indicates that all the pressurized oxygen has been removed from the flowmeter. Turn off the flowmeter. The gauge on the regulator should read zero with

Skill Drill 11-6 Placing an Oxygen Cylinder Into Service

Step 1

Inspect the cylinder and its markings. If the cylinder was commercially filled, it will have a plastic seal around the valve stem covering the opening in the stem. Remove the seal, and inspect the opening to make sure that it is free of dirt and other debris. The valve stem should not be sealed or covered with adhesive tape or any petroleum-based substances. These can contaminate the oxygen and can contribute to combustion when mixed with pressurized oxygen.

"Crack" the cylinder by slowly opening and then reclosing the valve to help make sure that the dirt particles and other possible contaminants do not enter the oxygen flow. Never face the tank toward yourself or others when cracking the cylinder. Open the tank by attaching a tank key (wrench) to the valve and rotating the valve counterclockwise. You should be able to hear clearly the rush of oxygen coming from the tank. Close the tank by rotating the valve clockwise.

Step 2

Attach the regulator/flowmeter to the valve stem after clearing the opening. On one side of the valve stem, you will find three holes. The larger one, on top, is a true opening through which the oxygen flows. The two smaller holes below it do not extend to the inside of the tank. They provide stability to the regulator. Following the design of the pin-indexing system, these two holes are very precisely located in positions that are unique to oxygen cylinders.

Above the pins on the inside of the collar is the actual port through which oxygen flows from the cylinder to the regulator. A metal-bound elastomeric sealing washer (also called a gasket) is placed around the oxygen port to optimize the airtight seal between the collar of the regulator and the valve stem. In the past, crush gaskets made of plastic and nylon were used, but are no longer recommended. If used, crush gaskets can be used only once and then they must be replaced.

Skill Drill 11-6 Placing an Oxygen Cylinder Into Service (*continued*)

Step 3

Place the regulator collar over the cylinder valve, with the oxygen port and pin-indexing pins on the side of the valve stem that has the three holes. Open the screw bolt just enough to allow the collar to fit freely over the valve stem. Move the regulator so that the oxygen port and the pins fit into the correct holes on the valve stem. The screw bolt on the opposite side should be aligned with the dimple depression. As you hold the regulator securely against the valve stem, hand tighten the screw bolt until the regulator is firmly attached to the cylinder. At this point, you should not see any open spaces between the sides of the valve stem and the interior walls of the collar.

© Jones & Bartlett Learning.

Step 4

With the regulator firmly attached, open the cylinder completely, check for air leaking from the regulator–oxygen cylinder connection, and read the pressure level on the regulator gauge. Most portable cylinders have a maximum pressure of approximately 2,000 psi. Most EMS systems consider a cylinder with less than 500 to 1,000 psi to be too low to keep in service. Learn your department's policies in this regard and follow them.

The flowmeter will have a second gauge or a selector dial that indicates the oxygen flow rate. Several popular types of devices are widely used. Attach the selected oxygen device to the flowmeter by connecting the universal oxygen connecting tubing to the "Christmas tree" (so called because of its shape) nipple on the flowmeter. Most oxygen-delivery devices come with this tubing permanently attached; however, some oxygen masks do not. You must attach this tubing to the oxygen-delivery device if it is not already attached.

the tank valve closed. This confirms that there is no pressure left above the valve stem. As long as there is a pressure reading on the regulator gauge, it is not safe to remove the regulator from the valve stem.

Hazards of Supplemental Oxygen

Oxygen does not burn or explode. However, it supports combustion. The more oxygen that is around,

the faster the combustion process. A small spark, even a glowing cigarette, can become a flame in an oxygen-rich atmosphere. Therefore, you must keep any possible source of fire away from the area while oxygen is in use. Make sure the area is adequately ventilated, especially in industrial settings where hazardous materials may be present and where sparks are easily generated. Be extremely cautious in any enclosed environment in which oxygen is being

administered because an oxygen-rich environment increases the chance of fire if a spark or flame is introduced. A smoking bystander or a vehicle extrication that generates sparks are possible ignition sources. Never leave an oxygen cylinder standing unattended. The cylinder could be knocked over, injuring the patient or damaging the regulator.

Oxygen Toxicity

The administration of oxygen to patients is a common practice. Although many patients in the prehospital environment require high concentrations of oxygen, not all patients do. Excessive supplemental oxygen can have a detrimental effect on patients with certain illnesses (ie, COPD, bronchopulmonary dysplasia, cerebrovascular accident [stroke], and myocardial infarction).

Recent research has shown that although the administration of oxygen benefits many patients and is rarely problematic, high concentrations of oxygen are potentially harmful for a select population. **Oxygen toxicity** refers to damage to cellular tissue as a result of excessive oxygen levels in the blood. Previously, high concentrations of oxygen were thought to benefit all patients in the prehospital environment. However, current evidence suggests that increased cellular oxygen levels contribute to the production of oxygen free radicals. These radicals may result in tissue damage and cellular death in some patients.

The International Liaison Committee on Resuscitation guidelines published by the American Heart Association recognize there may be negative effects of oxygen toxicity and recommend that oxygen be administered to patients experiencing signs of a myocardial infarction when they have signs of heart failure, are short of breath, or have a room air oxygen saturation less than or equal to 94%. In addition, patients experiencing signs of shock should be placed on oxygen. Hypoxemia is immediately life-threatening, whereas oxygen toxicity is not.

Tailor oxygen therapy to patient needs and use caution with administration. Understand that hypoxemia is much worse than oxygen toxicity; when in doubt, or if unable to measure oxygen saturation reliably, supplemental oxygen should be administered. Consider the use of ETCO_2 , especially in instances of head injury, poor perfusion, or carbon monoxide exposure.

Oxygen-Delivery Devices

In general, the oxygen-delivery equipment that is used in the field should be limited to nonrebreathing masks, bag-mask devices, and nasal cannulas, depending on local protocol. However, you may encounter other devices during transports between medical facilities. Flow rates for various oxygen-delivery devices are shown in **TABLE 11-9**.

Nonrebreathing Mask

The **nonrebreathing mask** is the preferred device to use when giving oxygen in the prehospital setting to patients who have adequate tidal volume but are suspected of having or are showing signs of hypoxia. Contraindications include apnea and poor respiratory effort. The nonrebreathing mask delivers oxygen passively and requires adequate tidal volume for the oxygen to be effectively drawn into the lungs. With a good mask-to-face seal and a flow rate of 15 L/min, it is capable of providing up to 90% inspired oxygen.

The nonrebreathing mask is a combination mask and reservoir bag system. Oxygen fills a reservoir bag that is attached to the mask by a one-way valve (**FIGURE 11-40**). The system is called a nonrebreathing mask because the exhaled gas escapes through flapper valve side ports covered by a one-way disk at the cheek areas of the mask. The valve between the mask and reservoir prevents the patient from rebreathing exhaled gases. The patient inhales enriched oxygen from the reservoir bag rather than residual air.

In this system, you must be sure that the reservoir bag is full before the mask is placed on the

TABLE 11-9 Oxygen-Delivery Devices

Device	Flow Rate	Oxygen Delivered
Nasal cannula	1 to 6 L/min	24% to 44%
Nonrebreathing mask	10 to 15 L/min	Up to 90%
Bag-mask device with reservoir	15 L/min	Nearly 100%
Mouth-to-mask device	15 L/min	Nearly 55%

FIGURE 11-40 The nonrebreathing mask contains flapper valve ports at the cheek areas of the mask to prevent the patient from rebreathing exhaled air.

© Jones & Bartlett Learning.

patient. Adjust the flow rate so that the bag does not fully collapse when the patient inhales, to approximately two-thirds of the bag volume, or 12 to 15 L/min. Make sure the bag stays inflated. Should the bag collapse when the patient inhales, increase the flow rate of oxygen. In addition, if oxygen therapy is discontinued, remove the mask from the patient's face. Leaving the mask in place while oxygen is not flowing allows the patient to rebreathe exhaled carbon dioxide. Use a pediatric mask, which has a smaller reservoir bag, for infants and children because they inhale a smaller volume.

Nasal Cannulas

A **nasal cannula** delivers oxygen through two small, tubelike prongs that fit into the patient's nostrils (**FIGURE 11-41**). This device can provide 24% to 44% inspired oxygen when the flowmeter is set at 1 to 6 L/min. For the comfort of your patient, flow rates above 6 L/min are not recommended with the nasal cannula.

A nasal cannula is ineffective for patients with poor respiratory effort, severe hypoxia, apnea, or mouth breathing. The primary use of a nasal cannula in the prehospital setting is for a patient who will not tolerate a nonrebreathing mask. In addition, a nasal cannula would be appropriate for patients requiring long-term oxygen therapy for certain diseases (such as COPD) whose current complaint is unrelated to their respiratory disease.

The advantage of a nasal cannula is that it is well tolerated. Even patients who are claustrophobic can

FIGURE 11-41 The nasal cannula delivers oxygen directly through the nostrils.

© MedStockPhotos/Alamy Stock Photo.

tolerate the nasal cannula. Unfortunately, the types of nasal cannulas available in the out-of-hospital environment do not deliver high volumes or high concentrations of oxygen.

The nasal cannula delivers dry oxygen directly into the nostrils. Therefore, when you anticipate a long transport time, you should consider the use of humidification.

Partial Rebreathing Mask

The **partial rebreathing mask** is similar to a nonrebreathing mask except that there is no one-way valve between the mask and the reservoir. Consequently, patients rebreathe a small amount of their exhaled air. This has some benefit when you want to increase the patient's partial pressure of carbon dioxide, which makes this the ideal mask for patients whom you think are experiencing hyperventilation syndrome. The oxygen enriches the air mixture and delivers a gas mix of approximately 80% to 90% oxygen. You can easily convert a nonrebreathing mask to a partial rebreathing mask by removing the one-way valve between the mask and the reservoir bag.

Venturi Mask

A Venturi mask has several attachments that enable you to vary the percentage of oxygen delivered to the patient while a constant flow is maintained from the regulator (**FIGURE 11-42**). The patient receives a highly specific concentration of oxygen

**FIGURE 11-42** A Venturi mask.

© Jones & Bartlett Learning. Courtesy of MIEMSS.

because of the Venturi principle, which causes air to be drawn into the flow of oxygen as it passes a hole in the line. The Venturi mask is a medium-flow device that delivers 24% to 40% oxygen, depending on the manufacturer.

The main advantage of the Venturi mask is the use of its fine adjustment capabilities in the long-term treatment of patients in physiologically stable condition. However, in the emergency setting, such fine adjustments are not necessary or even generally desirable. When you need to adjust the oxygen concentration in an emergency, it is typically done by adjusting the flow rate or changing the delivery device. For these reasons, Venturi masks are not frequently used in EMS or carried on ambulances.

Tracheostomy Masks

A patient with a **tracheostomy** does not breathe through the mouth and nose. A face mask or nasal cannula, therefore, cannot be used to treat these patients. Masks designed specifically for patients with tracheostomies cover the tracheostomy hole and have a strap that goes around the neck. These masks are usually available in intensive care units, where many patients have tracheostomies, and may not be available in an emergency setting. If you do not have a tracheostomy mask, you can improvise by placing a face mask over the stoma. Even though the mask is shaped to fit the face, you can usually get an adequate fit over the patient's neck by adjusting the strap (**FIGURE 11-43**).

**FIGURE 11-43** If you do not have a tracheostomy mask, use a face mask instead.

© Jones & Bartlett Learning.

**FIGURE 11-44** Administering humidified oxygen may be preferred with long transport times. However, this type of oxygen-delivery system is not used in all EMS systems.

© Jones & Bartlett Learning.

Oxygen Humidifiers

Some EMS systems provide humidified oxygen to patients during transport (**FIGURE 11-44**), especially patients receiving long-term oxygen therapy. A sterile water reservoir is needed for humidifying the

oxygen. However, humidified oxygen is usually indicated only for long-term oxygen therapy; prolonged transport time; and conditions such as croup, epiglottitis, and bronchiolitis. Many EMS systems do not use humidified oxygen in the prehospital setting, especially if their transport times to the hospital are short. Always refer to local protocols for guidance involving patient treatment issues.

Words of Wisdom

A nebulizer with saline or sterile water placed in the medication chamber may be used in place of humidified oxygen. Simply attach an oxygen mask to the aerosol chamber and set the flowmeter at 6 L/min.

Assisted and Artificial Ventilation

A patient who is not breathing needs artificial ventilation and 100% supplemental oxygen. Assisted and artificial ventilation are probably the most important skills in EMS—at any level. Basic airway and ventilation techniques are extremely effective when administered appropriately. Mastery of these techniques is imperative.

Patients who are breathing inadequately, such as patients who are breathing too fast or too slowly with reduced tidal volume, are typically unable to speak in complete sentences. An irregular breathing pattern will also require artificial ventilation to assist patients in maintaining adequate minute volume. Keep in mind that fast, shallow breathing can be just as dangerous as extremely slow breathing. Fast, shallow breathing moves air primarily in the larger airway passages (dead air space) and does not allow for adequate exchange of air and carbon dioxide in the alveoli. Signs of altered mental status and inadequate minute volume are indications for assisted ventilation. In addition, excessive accessory muscle use and fatigue from labored breathing are signs of potential respiratory failure. Patients exhibiting these signs need immediate treatment. Two treatment options are available for patients in severe respiratory distress or respiratory failure: assisted ventilation and **continuous positive airway pressure (CPAP)**. The purpose of assisted ventilation is to improve the overall oxygenation and

ventilatory status of the patient. CPAP is discussed later in this chapter; the focus of this section will be on assisted ventilation.

Words of Wisdom

Methods of ventilation (listed in order of preference):

- Mouth-to-mask with one-way valve
- Two-person bag-mask device with reservoir and supplemental oxygen
- Manually triggered ventilation (MTV) device (flow-restricted, oxygen-powered ventilation device)
- One-person bag-mask device with oxygen reservoir and supplemental oxygen

Note: This order of preference has been stated because research has demonstrated that personnel who infrequently ventilate patients have great difficulty maintaining an adequate seal between the mask and the patient's face.

Words of Wisdom

Ventilation rates for an apneic patient with a pulse:

- Adult:** 1 breath every 6 seconds
- Child:** 1 breath per 2 to 3 seconds
- Infant:** 1 breath per 2 to 3 seconds

Follow these steps to assist a patient with ventilation using a bag-mask device. Remember to follow standard precautions as needed when managing the patient's airway.

1. Explain the procedure to the patient.
2. Place the mask over the patient's nose and mouth.
3. Squeeze the bag each time the patient breathes, maintaining the same rate as the patient, and coaching the patient as needed.
4. After the initial 5 to 10 breaths, slowly adjust the rate and deliver an appropriate tidal volume.
5. Adjust the rate and tidal volume to maintain an adequate minute volume.

Artificial Ventilation

Without immediate treatment, patients who are in respiratory arrest will die. However, the act of breathing for a patient, or artificial ventilation, is

not a skill you should take lightly. After you determine that a patient is not breathing, you should begin artificial ventilation immediately. The methods that you may use to provide artificial ventilation include the mouth-to-mask technique; a one-, two-, or three-person bag-mask device; and the **manually triggered ventilation (MTV) device**.

Normal Ventilation Versus Positive-Pressure Ventilation

It is important to understand that although artificial ventilations are necessary to sustain life, they are not the same as normal breathing. As discussed earlier, the act of air moving in and out of the lungs is based on pressure changes within the thoracic cavity. During normal ventilation, the diaphragm contracts and negative pressure is generated in the chest cavity. This essentially sucks air into the chest through the trachea in an attempt to equalize the pressure in the chest with the atmospheric pressure. However, positive-pressure ventilation generated by a device, such as a bag-mask device, forces air into the chest cavity from the external environment, rather than based on pressure changes. This difference between normal ventilation and positive-pressure ventilation can create some challenges (**TABLE 11-10**).

The physical act of the chest wall expanding and retracting during breathing serves to aid the circulatory system in returning blood to the heart. During normal ventilation, the chest wall movement works similar to a pump. The pressure changes in the thoracic cavity help draw venous return back to the heart. However, positive-pressure ventilation causes the walls of the chest cavity to push out of their normal anatomic shape. As a result, there is an increase in the overall intrathoracic pressure within the chest cavity. This pressure increase affects the venous return of blood to the heart. The blood flow is decreased due to the increased pressure in the chest. This causes decreased venous return to the heart, and the amount of blood pumped out of the heart is reduced. Therefore, it is imperative that AEMTs regulate the rate and volume of artificial ventilations to avoid overdistention of the chest wall and thus help prevent this decrease in cardiac output.

Another difference between normal ventilation and positive-pressure ventilation is the control of airflow. When a person breathes, air enters the trachea and, generally, not the esophagus. However, the force generated from positive-pressure ventilation allows air to enter not only the trachea, but also the esophagus. Ventilations that are too forceful can

TABLE 11-10 Normal Ventilation Versus Positive-Pressure Ventilation		
	Normal Ventilation	Positive-Pressure Ventilation
Air movement	Air is drawn into the lungs due to the negative intrathoracic pressure created when the diaphragm contracts.	Air is forced into the lungs by means of mechanical ventilation.
Blood movement	Normal breathing allows blood to naturally be pulled back to the heart.	Intrathoracic pressure is increased, not allowing blood to be drawn back to the heart as efficiently. This causes the amount of blood pumped by the heart to be reduced.
Airway wall pressure	Not affected during normal breathing	More volume is required to have the same effects as normal breathing. As a result, the walls are pushed out of their normal anatomic shape.
Esophageal opening pressure	Not affected during normal breathing	Air is forced into the stomach, causing gastric distention that could result in vomiting and aspiration.
Overventilation	Overventilation is not typical of normal breathing.	Forcing volume and rate results in increased intrathoracic pressure, gastric distention, and a decrease in cardiac output (hypotension).

result in excessive air in the stomach. This potential complication, called gastric distention, will be discussed later in this chapter.

Mouth-to-Mouth and Mouth-to-Mask Ventilation

As you learned in your CPR course, mouth-to-mouth ventilation is routinely performed with a barrier device, such as a mask or face shield. A **barrier device** is a protective item that features a plastic barrier placed on a patient's face with a one-way valve to prevent the backflow of secretions, vomitus, and gases. Barrier devices provide adequate protection (**FIGURE 11-45**).

Mouth-to-mouth is the most basic form of ventilation. Indications for this type of ventilation include apnea when other ventilation devices are not available.

Although mouth-to-mouth ventilation requires no special equipment and can deliver effective tidal volume, there are other methods of providing artificial ventilation that are safer for the rescuer. The disadvantages of the mouth-to-mouth technique include the risk of unknown communicable diseases and psychological barriers associated with this method.

Mouth-to-mask ventilation, or ventilation using another barrier device, is preferred over the mouth-to-mouth technique (although neither technique should be used during active community transmission of respiratory viral disease, such as COVID-19). Advantages of using a mask include

FIGURE 11-45 Barrier devices, such as a plastic shield or pocket mask with a one-way valve, provide adequate protection.

© American Academy of Orthopaedic Surgeons.

Safety

Ventilation techniques that use the provider's mouth create an unacceptable risk of disease transmission in the context of community transmission of severe respiratory illness such as COVID-19. Avoiding these techniques is of paramount importance. Bring the correct equipment with you from the ambulance when responding on a call that potentially involves an apneic patient or a patient with inadequate breathing.

placing a physical barrier between the rescuer's mouth and the patient's mouth. Most masks offer a one-way valve to prevent the rescuer's exposure to blood and body fluids. It is also easier to secure an effective seal with a mask because the rescuer can use both hands, which enables the provision of adequate tidal volume to the patient.

A mask with an oxygen inlet provides oxygen during mouth-to-mask ventilation to supplement the air from your own lungs. Remember that the gas you exhale contains 16% oxygen, which is adequate to sustain the patient's life. With the mouth-to-mask system, however, the patient gets the additional benefit of substantial oxygen enrichment with inspired air.

The mask may be shaped like a triangle or a doughnut, with the apex (top) placed across the bridge of the nose. The base (bottom) of the mask is placed in the groove between the lower lip and the chin. In the center of the mask is a chimney with a 15-mm connector.

Follow the steps in **SKILL DRILL 11-7** to use mouth-to-mask ventilation.

You know that you are providing adequate ventilation if you see the patient's color improving and chest rise adequately and you do not meet resistance when ventilating. Feel for resistance of the patient's lungs as they expand. You should also hear and feel air escape as the patient exhales. Make sure that you are providing the correct number of breaths per minute for the patient's age. Color improvement may not be instantaneous.

To increase the oxygen concentration, administer high-flow oxygen at 15 L/min through the oxygen inlet valve of the mask. This, when combined with your exhaled breath, will deliver approximately 55% oxygen to the patient. Ventilate over 1 second to produce visible chest rise.

Skill Drill 11-7 Mouth-to-Mask Ventilation

Step 1

Kneel at the patient's head. Open the airway using the head tilt–chin lift maneuver or the jaw-thrust maneuver if trauma is suspected. Insert an oral or nasal airway, if possible, to help maintain airway patency. Connect the one-way valve to the face mask and place the mask on the patient's face. Make sure the top is over the bridge of the nose and the bottom is in the groove between the lower lip and the chin. Hold the mask in position by placing your thumbs over the top part of the mask and your index fingers over the bottom half. Grasp the lower jaw with the remaining three fingers on each hand, making an airtight seal by pulling the lower jaw into the mask. Maintain an upward and forward pull on the lower jaw with your fingers to keep the airway open. This method of securing the mask to the patient's face is known as the EC-clamp method.

Step 2

Take a deep breath and exhale through the open port of the one-way valve. Breathe slowly into the patient's mask until you observe adequate chest rise.

© Jones & Bartlett Learning.

Step 3

Remove your mouth from the valve, and watch the patient's chest fall during passive exhalation.

The Bag-Mask Device

With an oxygen flow rate of 15 L/min and an adequate seal, a **bag-mask device** with an oxygen reservoir can deliver nearly 100% oxygen (**FIGURE 11-46**).

Most bag-mask devices on the market include modifications or accessories (reservoirs) that permit the delivery of oxygen concentrations approaching 100%. However, the device can deliver only as much

FIGURE 11-46 A bag-mask device with an oxygen reservoir can deliver nearly 100% oxygen if a good seal between the mouth and mask is achieved and if supplemental oxygen is used.

© American Academy of Orthopaedic Surgeons.

volume as you can squeeze out of the bag by hand. The bag-mask device provides less tidal volume than mouth-to-mask ventilation; however, it delivers a much higher oxygen concentration.

The bag-mask device is the most common method used to ventilate patients in the field. An

experienced AEMT will be able to supply adequate tidal volumes with a bag-mask device. Use of the device, however, is a difficult skill to master. Mask seal on a medical patient may be difficult to obtain and maintain with only one rescuer. Because it takes two hands to perform a jaw-thrust maneuver, it takes two rescuers to use a bag-mask device on a trauma patient unless an advanced airway has been inserted already. The amount of tidal volume and the concentration of oxygen delivered to the patient are dependent on mask seal integrity. Be sure to practice on ventilation manikins several times before using a bag-mask device on a patient.

A bag-mask device should be used when you need to deliver high concentrations of oxygen to patients who are not ventilating adequately. The bag-mask device may be used with or without oxygen. However, it is most effective when used with supplemental oxygen and a reservoir. Depending on the patient's LOC, you should use an oral or a nasal airway adjunct in conjunction with the bag-mask device to maintain patency of the patient's airway. Generally, a bag-mask device should not be used on any patient who is intolerant of its use;

YOU are the Provider

Part 4

Your partner states that he is now able to ventilate the patient with ease, and you note adequate chest rise and fall and an increase in the patient's pulse oximetry level. You contact dispatch and are advised that the transporting ambulance is approximately 4 minutes away and requests that you switch to the fireground channel and provide a quick update to the ambulance. You change channels on your radio and, after making contact, you provide a quick update to the responding paramedics. They ask whether the patient had any abnormal respiratory patterns before insertion of the airway, to which you reply "negative." They then advise that they are pulling into the parking lot now. As the paramedics arrive, you give a more detailed report and assist in loading the patient onto their stretcher. They thank you for your prompt treatment and release you back in service.

Recording Time: 14 Minutes

Respirations	12 breaths/min; assisted
Pulse	112 beats/min
Skin	Cool and dry
Blood pressure	100/54 mm Hg
Oxygen saturation (SpO₂)	88% on 15 L/min
Pupils	PERRLA

7. What are some possible respiratory patterns you may encounter?
8. If the patient's respiratory rate increases to an acceptable level, should the King LT airway be removed?

however, if the patient is responsive and breathing inadequately (that is, reduced tidal volume), ventilatory assistance with a bag-mask device will be required to maintain adequate minute volume. In such cases, you must explain the procedure to the patient, advising that each time the patient takes a breath, you will squeeze the bag-mask to assist breathing efforts.

Bag-Mask Device Components

All adult bag-mask devices should have the following components and characteristics:

- A disposable self-refilling bag
- No pop-off valve or, if one is present, the capability of disabling the pop-off valve
- An outlet valve that is a true valve for nonrebreathing
- An oxygen reservoir that permits delivery of a high concentration of oxygen
- A one-way, no-jam inlet valve system that provides an oxygen inlet flow at a maximum of 15 L/min with standard 15/22-mm fittings for face mask and/or advanced airway (ie, ET tube, laryngeal mask airway, King LT, i-gel)
- A transparent face mask
- Ability to perform under extreme environmental conditions, including extreme heat and cold

The total amount of gas in the reservoir bag of an adult bag-mask device is usually 1,200 to 1,600 mL. The pediatric bag contains 500 to 700 mL, and the infant bag holds 150 to 240 mL.

The volume of air (oxygen) to deliver to the patient is based on one key observation—visible chest rise. A delivered tidal volume of 500 to 600 mL (6 to 7 mL/kg) per breath will produce visible chest rise in most adults. When using a bag-mask device, whether supplemental oxygen is attached to it or not, you should deliver each breath during a period of 1 to 2 seconds—just enough to produce visible chest rise—at the appropriate rate. Breaths that are delivered too forcefully or too fast can result in two negative effects: gastric distention (and the associated risks of vomiting and aspiration) and decreased blood return to the heart because of increased intrathoracic pressure.

Improper technique, an ineffective mask-to-face seal, or the presence of gastric distention may cause you to deliver inadequate tidal volume and oxygen.

Safety

When ventilating a patient who may be positive for COVID-19, or any patient with signs or symptoms of a respiratory illness, use a high-efficiency particulate air (HEPA) filter on the bag-mask device to prevent aerosolizing the virus (**FIGURE 11-47**).

FIGURE 11-47 A bag-mask device with a HEPA filter attached.

Used with permission from Ambu A/S.

Training and practice are key to the proper use of a bag-mask device.

Bag-Mask Device Technique

Whenever possible, you and your partner should work together to provide ventilation with the bag-mask device. One AEMT can maintain a good mask seal by securing the mask to the patient's face with two hands while the other AEMT squeezes the bag. Ventilation using a bag-mask device is a challenging skill: it may be very difficult for one EMS provider to maintain a proper seal between the mask and the face with one hand while squeezing the bag well enough to deliver an adequate volume to the patient. Also, performance of this skill depends on having enough personnel to carry out other actions that need to be done at the same time, such as chest compressions, putting the stretcher in place, or helping to lift the patient onto the stretcher.

There are three major considerations when using a bag-mask device to ventilate a patient. First, the typical adult bag-mask device holds a much

Special Populations

The flat nasal bridge of pediatric patients makes achieving an effective mask-to-face seal more difficult. Compressing the mask against the face to improve mask seal may result in obstruction. The best mask seal is achieved by the two-person ventilation method with jaw displacement.

For full-term neonates and infants, use a pediatric bag-mask device with a minimum tidal volume of 450 mL. In children (ages 1 year to the onset of puberty [ages 12 to 14 years]), consider the size of the child when determining bag size. You may use an adult bag-mask device with a 1,500-mL tidal volume, but a pediatric bag-mask device is preferred. Children older than 12 to 14 years require the adult-size bag-mask device for adequate ventilation. Choose a size to ensure a proper mask fit. The mask should reach from the bridge of the nose to the cleft of the chin. A length-based resuscitation tape may also be used to determine the proper size of the bag-mask device for pediatric patients who weigh up to 75 pounds (34 kg).

When you are ventilating a pediatric patient, ensure a proper mask seal by using the EC-clamp technique (as discussed previously in this chapter). Avoid placing pressure on the soft area under the chin. Deliver each ventilation over 1 second—just enough to produce visible chest rise. *Do not overinflate.* Deliver one breath every 2 to 3 seconds, and allow adequate time for exhalation. While ventilating, look for adequate chest rise. Listen for breath sounds at the third intercostal space on the midaxillary line bilaterally. Also assess for improvement in skin color and pulse rate.

larger volume of air than is needed. Not only can excessive volume cause barotrauma, it can also result in an increase in intrathoracic pressure that decreases venous return to the heart. You should squeeze the bag slowly, over 2 seconds, and just until you have adequate chest rise. Second, quick, forceful delivery of breaths may result in gastric distention as it only takes a small amount of pressure to override the lower esophageal sphincter. This may trigger regurgitation of stomach contents or may expand the stomach, causing it to compress the diaphragm and impede ventilation by inhibiting lung expansion. And last, be conscientious of the rate of delivery of breaths. Hyperventilation is helpful in only a few specific incidences. If possible, monitor ETCO_2 and maintain at 35 to 45 mm Hg. If

the ETCO_2 drops below 35 mm Hg, you are ventilating too fast; if it rises above 45 mm Hg, you are ventilating too slowly.

Follow these steps to use the two-person bag-mask device technique:

1. Kneel above the patient's head. If possible, your partner should be at the side of the head to squeeze the bag while you hold a seal between the mask and the patient's face with two hands. Select the proper size mask.
2. Maintain the patient's neck in a hyperextended position unless you suspect a cervical spine injury. In that case, you should immobilize the patient's head and neck in a neutral position and use the jaw-thrust maneuver. Have your partner squeeze the bag.
3. Connect the bag-mask device to supplemental oxygen.
4. Open the patient's mouth, and suction as needed. Insert an oral or nasal airway to maintain airway patency.
5. Place the mask on the patient's face. Ensure the top is over the bridge of the nose and the bottom is in the groove between the lower lip and the chin. If the mask has a large, round cuff around the ventilation port, center the port over the patient's mouth. Inflate the collar to obtain a better fit and seal to the face if necessary.
6. Bring the lower jaw up to the mask with your last three fingers. Pull the face up to the mask instead of pushing the mask onto the face. This will help to maintain an open airway. Make sure you do not grab the fleshy part of the neck because you may compress structures and create an airway obstruction. If you think the patient may have a spinal injury, make sure your partner immobilizes the cervical spine as you move the lower jaw.
7. Hold the mask in place while your partner squeezes the bag with two hands until the patient's chest visibly rises (**FIGURE 11-48**). If a spinal injury is suspected, stabilize the patient's head and neck with your forearms while maintaining an adequate mask-to-face seal with your hands. Continue squeezing the bag once every 6 seconds for adults and once every 2 to 3 seconds for infants and children.
8. If you are alone, then place your thumb and index finger as high up on the mask as you can to form a C. Maintain the airway by lifting

the bony prominence of the chin with your remaining fingers to form an E. Do not push the mask to the face; pull the lower jaw into the mask. This is known as the EC-clamp method and can be used to maintain an effective face-to-mask seal (**FIGURE 11-49**). Use the head tilt–chin lift maneuver to make sure the neck is extended. Squeeze the bag with your other hand in a rhythmic manner once every 6 seconds for adults and once every 2 to 3 seconds for infants and children.

9. Observe for gastric distention, changes in compliance of the bag with ventilation, and improvement or deterioration of the patient's condition.

FIGURE 11-48 With two-person bag-mask device ventilation, you should hold the mask in place while your partner squeezes the bag with two hands until the patient's chest rises.

FIGURE 11-49 Maintain the seal of the mask to the face using the EC-clamp technique if you must ventilate alone.

© Jones & Bartlett Learning.

When using the bag-mask device to assist ventilation, you should squeeze the bag as the patient breathes in. Then, for the next 5 to 10 breaths, slowly adjust the rate and delivered tidal volume until an adequate minute volume is achieved.

To assist respirations of a patient who is breathing too fast (hyperventilation) with reduced tidal volume, you must first explain the procedure to the patient if the patient is coherent. Initially assist respirations at the rate at which the patient has been breathing, squeezing the bag each time the patient inhales. Then, for the next 5 to 10 breaths, slowly adjust the rate and the delivered tidal volume until an adequate minute volume is achieved.

As you are assisting ventilation with a bag-mask device, evaluate the effectiveness of your ventilations (**TABLE 11-11**). Artificial ventilation is not adequate if the patient's chest does not rise and fall

TABLE 11-11 Evaluating Effectiveness of Artificial Ventilations	
Adequate artificial ventilation ^a	• Visible and equal chest rise and fall with ventilation • Breath sounds can be heard during auscultation of the chest • Ventilations delivered at the appropriate rate • 10 breaths/min for adults • 20 to 30 breaths/min for infants and children • In patients with ongoing CPR and an advanced airway in place, 1 breath every 6 seconds • Pulse rate returns to normal range • Patient's color is improving • Oxygen saturation level improves
Inadequate artificial ventilation	• Minimal or no chest rise and fall • Breath sounds cannot be heard during auscultation of the chest • Ventilations delivered too fast or too slowly for patient's age • Pulse rate does not return to normal range • Patient's color remains cyanotic or mottled or deteriorates • Oxygen saturation level does not improve

Abbreviation: CPR, cardiopulmonary resuscitation

^aIn patients who are apneic with a pulse.

© Jones & Bartlett Learning.

with each ventilation or the rate of ventilation is too slow or too fast for the patient's age, or the heart rate does not return to normal. If the patient's chest does not rise and fall, you may need to reposition the head or insert an airway adjunct.

If the patient's stomach, rather than the chest, seems to be rising and falling, you should reposition the head. In a patient with a possible spinal injury, you should reposition the jaw rather than the head. If too much air is escaping from under the mask, reposition the mask for a better seal. If the patient's chest still does not rise and fall after you have made these corrections, check for an airway obstruction. If an obstruction is not present, you should attempt ventilation with another airway device.

Advanced airway techniques are beneficial when ventilation with basic means is not effective, the patient has a cervical spine injury, or the patient's condition warrants.

MTV Devices

Another method of providing artificial ventilation is with the MTV device, also known as flow-restricted, oxygen-powered ventilation devices. They are mainly used to ventilate apneic or hypoventilating patients, although these devices can also be used to provide supplemental oxygen to breathing patients. MTV devices have a demand valve that is triggered by the negative pressure generated by inhalation (**FIGURE 11-50**). This valve automatically delivers 100% oxygen as the patient begins to inhale and stops the flow of gas at the end of the inspiratory

phase of the respiratory cycle. Because the MTV device makes an airtight seal with the patient's face, the gas that the patient inspires is almost 100% oxygen.

The major advantage to this device is that it allows a single rescuer to use both hands to maintain a mask-to-face seal while providing positive-pressure ventilation to a spontaneously breathing patient. It also reduces rescuer fatigue associated with using a bag-mask device on extended transports. However, findings suggest that MTV devices are associated with difficulty in maintaining adequate ventilation without assistance and should not be used routinely because of the high incidence of gastric distention and possible damage to structures within the chest cavity. Another disadvantage is that a special unit and additional training are required when using the MTV device on infants and children. Because the rescuer is not actively squeezing a bag, it is virtually impossible to assess for lung compliance. As a result, the rescuer should take extra care when ventilating; the high ventilatory pressures generated by the device may damage lung tissue if not carefully monitored.

Safety

Learning how to use MTV devices correctly requires proper training and considerable practice. As with bag-mask devices, you must make sure there is an airtight fit between the patient's face and the mask. The amount of pressure that is necessary to ventilate a patient adequately will vary according to the size of the patient, the patient's lung volume, and the condition of the lungs. Pressures that are too great can cause a pneumothorax. Always follow local medical protocols carefully when you use these devices.

FIGURE 11-50 A manually triggered ventilation device can provide up to 100% oxygen.

© Jones & Bartlett Learning.

Automatic Transport Ventilators/Resuscitators

The **automatic transport ventilator (ATV)** allows the variables of ventilation—ventilator rate, tidal volume, and peak inspiratory time—to be precisely set; these features allow for consistent ventilation (**FIGURE 11-51**). Many types of ATVs are available, some with basic settings and others with more advanced settings and features. The steps for using the ATV are as follows:

1. Attach the ATV to the wall-mounted oxygen source.

FIGURE 11-51 An automatic transport ventilator.

Provided with permission by ZOLL Medical.

2. Set the ventilator rate, tidal volume, and peak inspiratory time on the ATV as appropriate for the patient's condition.
3. Connect the ATV to the 15/22-mm fitting on the ET tube or other advanced airway device.
4. Auscultate the patient's breath sounds, and observe for equal chest rise to ensure adequate ventilation.

Although the ATV lacks the sophisticated control of a hospital ventilator, it frees your hands to perform other tasks, such as maintaining a mask seal or ensuring continued patency of the airway. You can even perform other, non-airway-related tasks if the patient is intubated and being ventilated with the ATV. However, even though an ATV is helpful, you must always have a bag-mask device and mask prepared and ready for use should the ATV malfunction.

Most models have adjustments for respiratory rate and tidal volume. In most cases, the respiratory rate is set at the midpoint or average for the

patient's age. The machine or respiratory therapist estimates tidal volume using a formula based on 6 to 7 mL/kg because ATVs are oxygen-powered and provide oxygen-enriched breathing gas. The tidal volume can be adjusted based on the patient's chest rise and physiologic response. The ATVs are considered volume-cycled-rate-controlled ventilators. This means that they deliver a preset volume at a preset ventilatory rate, although this does not guarantee that all the volume is being delivered to the lungs. In the event of cardiac arrest, you may need to revert to ventilations with a bag-mask device. The ATV is set at a fixed rate and will not cycle in conjunction with the timing of chest compressions.

The ATV is oxygen-powered, although some models may require an external power source. This device generally consumes 5 L/min of oxygen, unlike a bag-mask device that uses 15 to 25 L/min. In addition, the ATV has a pressure-relief valve, which can result in hypoventilation in patients with poor lung compliance, increased airway resistance, or airway obstruction. **Lung compliance** is the ability of the alveoli to expand when air is drawn in during inhalation; poor lung compliance is the inability of the alveoli to fully expand during inhalation. Remember that there is the possibility of barotrauma (trauma resulting from excessive pressure) if the relief valve fails or if ventilation is overzealous.

Continuous Positive Airway Pressure

CPAP is a noninvasive means of providing ventilatory support for patients experiencing respiratory distress. Many people with obstructive sleep apnea wear a CPAP unit at night to maintain their airway while they sleep. The use of CPAP in the prehospital environment has proven to be an excellent adjunct in the treatment of respiratory distress associated with obstructive pulmonary disease, acute bronchospasm, and acute pulmonary edema. Typically, many of the patients would be treated with advanced airway devices, such as ET intubation. Early intervention with CPAP is an alternative means for providing ventilatory assistance and can prevent the need for ET intubation, thereby improving the patient's chance of survival. Because of the simplicity of the device and its great benefit to patients, CPAP is becoming widely used in EMS.

CPAP increases pressure in the lungs, opens collapsed alveoli, pushes more oxygen across the alveolar membrane, and forces interstitial fluid back into the pulmonary circulation. The desired effect of CPAP is to improve pulmonary compliance and make spontaneous ventilation easier. The therapy is typically delivered through a face mask that is held to the head with a strapping system. A good seal with minimal leakage between the face and mask is essential.

The face mask is fitted with a pressure-relief valve that determines the amount of pressure delivered to the patient (such as 5 centimeters of water [cm H₂O]). This pressure results in a high inspiratory flow and the need to push a pressure valve open with exhalation. Although this may appear to require a great deal of effort from the patient, especially while in respiratory distress, many patients make a dramatic turnaround when CPAP is applied.

Indications for CPAP

CPAP is indicated for patients experiencing respiratory distress in which their own compensatory mechanisms cannot keep up with their oxygen demand. Although the condition of most patients improves after the application of CPAP, it is important to remember that CPAP is merely treating the symptoms and not necessarily the underlying pathology.

The following are some general guidelines for CPAP candidates:

- Patient alert and able to follow commands
- Obvious signs of moderate to severe respiratory distress (such as accessory muscle use, retractions, or tripod position) from an underlying disease such as heart failure with pulmonary edema, obstructive pulmonary disease (such as COPD), acute bronchospasm (such as in acute asthma), and suspected pneumonia
- Respiratory distress after a submersion incident
- Rapid breathing (more than 26 breaths/min), such that it affects overall minute volume
- Pulse oximetry reading of less than 90%

Whereas these guidelines should be considered when assessing the need for CPAP, it is important that you follow your local guidelines and protocols.

Contraindications to CPAP

CPAP has proven to be immensely beneficial to patients experiencing respiratory distress from acute pulmonary edema, acute bronchospasm, and obstructive pulmonary disease; however, there are times when CPAP is not appropriate.

The following are general contraindications for CPAP use:

- Patient unresponsive or otherwise unable to follow verbal commands
- Respiratory arrest or agonal respirations
- Patient unable to speak
- Patient unable to protect their own airway
- Hypoventilation (slow respiratory rate and/or reduced tidal volume)
- Hypotension (systolic blood pressure less than 90 mm Hg)
- Signs and symptoms of a pneumothorax or chest trauma (either blunt or penetrating)
- Closed head injury
- Facial trauma
- Cardiogenic shock
- Tracheostomy
- Active gastrointestinal bleeding, nausea, or vomiting
- History of recent gastrointestinal surgical procedure
- Patient unable to sit up
- Inability to properly fit the CPAP system mask and strap
- Excessive facial hair or dysmorphic facial features that can impede your ability to ensure a proper-fitting mask
- Patient cannot tolerate the mask

In addition, always reassess the patient for signs of deterioration and/or respiratory failure. CPAP is an excellent tool to assist with ventilation; however, not all patients will experience an improvement in condition with this device. After signs of respiratory

Safety

CPAP systems without viral filters may increase risk of aerosolization of secretions during sleep, which may increase the risk of these patients transmitting certain diseases, such as COVID-19 or tuberculosis, to people around them when they sleep.

failure become apparent or the patient is no longer able to follow commands, remove the CPAP device and initiate positive-pressure ventilation with a bag-mask device attached to high-flow oxygen.

Application of CPAP

Several varieties of CPAP units are available to EMS services; however, most follow the same general guidelines for use and setup. CPAP units are generally composed of a generator, a mask, a circuit that contains corrugated tubing, a bacteria filter, and a one-way valve. During the expiratory phase, the patient exhales against a resistance called **positive end-expiratory pressure (PEEP)**. PEEP maintains pressure in the lungs at the end of exhalation and keeps the open alveoli from collapsing. It also recruits, or opens, closed alveoli, which improves oxygenation by increasing the surface area for gas exchange. Within the CPAP generator is a valve that determines the amount of PEEP; however, some CPAP models have PEEP valves that connect separately. Depending on the device, the PEEP is controlled by manually adjusting the PEEP using a manometer or predetermined by a fixed setting on the PEEP valve. A PEEP of 5.0 to 10.0 cm H₂O is generally an acceptable therapeutic range for a patient

using CPAP, although it can be adjusted higher or lower if needed. Always consult the operations manual of a specific CPAP device for proper assembly instructions.

Because most CPAP units are powered by oxygen, it is important to have a full cylinder of oxygen when using CPAP. Some CPAP units use a continuous flow of oxygen, whereas others use oxygen on more of a demand basis. Continuously monitor the amount of available oxygen in your cylinder. Some CPAP units will empty a D cylinder in as little as 5 to 10 minutes. Therefore, proper planning for oxygen consumption is necessary when considering the application of CPAP. In addition, some newer CPAP devices allow the provider to adjust the fraction of inspired oxygen (FIO₂). Most CPAP devices are set to deliver a fixed FIO₂ of 30% to 35%; however, some can deliver as high as 80%.

Follow the steps in **SKILL DRILL 11-8** to use a CPAP.

Complications of CPAP

The application and administration of CPAP is a relatively easy process. However, some patients may find CPAP claustrophobic and will resist the application. As patients become more hypoxic, the

Skill Drill 11-8 Using CPAP

Step 1

Take standard precautions. Assess the patient for indications and contraindications for CPAP. Confirm the patient's blood pressure and explain the procedure. Check your equipment, then connect the circuit to the CPAP device.

Step 2

Connect the face mask to the circuit tubing. After the system is connected, look for an on/off button or switch. Some models have this feature. Confirm the device is powered on and working before you apply CPAP to the patient.

Skill Drill 11-8 Using CPAP (continued)

Step 3

Connect the tubing to the oxygen tank.

Step 4

Place the mask over the patient's mouth and nose, creating as much of an airtight seal as possible. Place the patient in a high Fowler position to facilitate breathing, and coach the patient through the initial application of the mask. To reduce some of the stress and anxiety associated with the application of CPAP, it may be beneficial to initially allow the patient to hold the mask to their face. Allow the patient to get used to the mask.

Step 5

After the mask is placed on the face and the patient adjusts to it, use the strapping mechanism to secure it to the patient's head. Ensure the seal between the mask and face remains intact. Consult the manufacturer's guidelines for specific strapping instructions.

Step 6

Adjust the PEEP valve and the FiO_2 level according to the manufacturer's recommendations to maintain adequate oxygenation and ventilation. With CPAP in place, the patient's oxygenation saturation level should improve, the work of breathing should decrease, the ease of speaking should increase, and breath sounds should improve. Constantly reassess the patient for signs of clinical deterioration and/or complications (ie, pneumothorax).

application of a mask to their face is sometimes perceived as suffocation, rather than helping them breathe. In any event, it is important to explain the application to patients and coach them through the process. Do not force the mask on patients. Forceful application will create a higher level of anxiety and increase oxygen demand. Coach patients through the application of CPAP, allowing them to adjust to the situation. Coaching patients is not always an easy task; it takes practice and a willingness to work closely with your patient during a rather difficult time.

Because of the high volume of pressure generated by CPAP, it is possible to cause a pneumothorax as a result of barotrauma. You should be aware of this risk and continually assess your patients for signs and symptoms of a pneumothorax.

In addition to pneumothoraces, increased pressure in the chest cavity can result in hypotension. As the intrathoracic pressure increases, venous blood returning to the heart (preload) meets resistance from the increased pressure in the chest, which can cause hypotension. Although this is not common with lower levels of CPAP, continuous monitoring of blood pressure is necessary.

As with any form of positive-pressure ventilation in the unprotected airway, air may enter the stomach, which increases the risk of vomiting and therefore the potential for aspiration.

Words of Wisdom

Bilevel positive airway pressure (BPAP), another form of noninvasive positive-pressure ventilation, is also used to treat patients with obstructive lung disease, acute bronchospasm, and acute pulmonary edema. Whereas CPAP delivers a single pressure (which is most beneficial to the patient during exhalation), BPAP delivers two pressures: a higher inspiratory positive airway pressure (IPAP), which opens the lower airways, and a lower expiratory positive airway pressure (EPAP), which helps keep the lower airways open. Common BPAP settings deliver 10 cm H₂O during inhalation and 5 cm H₂O during exhalation; the difference between the IPAP and EPAP is called pressure support. The indications, contraindications, and precautions for BPAP are the same as they are for CPAP. Follow your EMS system protocols regarding the use of BPAP and the desired IPAP and EPAP settings.

Special Considerations

Gastric Distention

Any form of artificial ventilation that blows air into the patient's mouth, as opposed to blowing air directly into the trachea via an ET tube, may result in inflation of the patient's stomach with air. Gastric distention (inflation of the patient's stomach with air) is especially likely to occur if excessive pressure is used to inflate the lungs, if ventilations are performed too fast or too forcefully, or if the airway is partially obstructed during ventilation attempts. The pressure in the airway forces open the esophagus, and air flows into the stomach. Gastric distention occurs most often in children but is common in adults as well.

A distended stomach is harmful for at least two reasons. First, it promotes regurgitation of stomach contents, which creates the potential for aspiration. Second, a distended stomach pushes the diaphragm upward into the chest, reducing the amount of space in which the lungs can expand.

Signs of gastric distention include an increase in the diameter of the stomach, an increasingly distended abdomen, and increased resistance to bag-mask ventilations. If you observe these signs, reassess and reposition the airway as needed and observe the chest for adequate rise and fall as you continue ventilating. In addition, limit ventilation times to 1 second or the time needed to produce adequate chest rise.

Laryngectomy, Tracheostomy, Stoma, and Tracheostomy Tubes

A **laryngectomy** is a surgical procedure in which the larynx is removed. This procedure is performed by making a tracheostomy, thus creating a stoma. The tracheal stoma is located in the midline of the anterior part of the neck. Surgical removal of the entire larynx is called **total laryngectomy**. A person who has undergone this procedure breathes through the stoma in the neck. Because a connection no longer exists between the patient's pharynx and lower airway, you cannot ventilate the patient through the nose and mouth with a bag-mask device or other face mask. The air blown into the mouth or nose can only go down the esophagus into the stomach; it will not reach the lower airway.

A **partial laryngectomy** entails surgical removal of a portion of the larynx. In practice, you may be

unable to tell whether a person has had a total or partial laryngectomy until you attempt artificial ventilation. As opposed to a total laryngectomy, artificial ventilation through the nose and mouth may still be effective after a partial laryngectomy.

Suctioning of a Stoma

You may encounter patients who require suctioning of thick secretions from the stoma. Failure to recognize and identify this need could result in hypoxia. It is not uncommon for a patient's stoma to become

occluded with mucous plugs. Patients with a laryngectomy have a less efficient cough and, therefore, have difficulty spontaneously clearing the stoma.

You must perform suctioning of the patient's stoma with extreme care, especially if you suspect laryngeal swelling. Even the slightest irritation of the tracheal wall can result in a violent **laryngospasm** and complete airway closure. Limit suctioning of the stoma to 10 seconds at a time.

The steps for suctioning a stoma are shown in **SKILL DRILL 11-9**.

Skill Drill 11-9 Suctioning of a Stoma

Step 1

Take standard precautions.

Step 2

Inject 3 mL of sterile saline through the stoma and into the trachea.

Step 3

Instruct the patient (if responsive) to exhale, and insert the catheter without providing suction until resistance is felt (no more than 12 cm).

© Jones & Bartlett Learning.

Step 4

Suction while withdrawing the catheter.

Ventilation of Stoma Patients

Neither the head tilt–chin lift nor the jaw-thrust maneuver is required for ventilating a patient with a stoma. If the patient has a stoma and no tracheostomy tube (discussed next) in place, then you can perform ventilation using the mouth-to-stoma (with a resuscitation mask) technique or with a bag-mask device. Techniques involving use of the rescuer's mouth should be avoided if other options are available, particularly in the context of active aerosol transmission of respiratory illness in a community, such as during the COVID-19 pandemic.

Regardless of the technique used, you should use an infant- or child-size mask to make an adequate seal over the stoma. Seal the patient's nose and mouth with one hand to prevent the leakage of air up the trachea. Release the seal of the patient's mouth and nose following each ventilation, allowing exhalation to occur through the upper airway. Two rescuers are needed to perform bag-mask device-to-stoma ventilation: one to seal the nose and mouth and the other to squeeze the bag-mask device. If you are unable to ventilate a patient who has a stoma, then try suctioning the stoma and mouth with a soft-tip (French) catheter before providing artificial ventilation through the nose and mouth. Note that this technique would work only if the patient had a partial laryngectomy, not if the patient had a total laryngectomy. If you seal the stoma during ventilation, then the ability to artificially ventilate the patient in this way may be improved, or it may help to clear any obstructions.

The steps for performing mouth-to-stoma ventilation with a resuscitation mask are shown in **SKILL DRILL 11-10**. Again, note that while it is essential for AEMTs to master this skill, ventilation techniques that do not require use of the provider's mouth are safer for patient and provider.

The steps for performing bag-mask device-to-stoma ventilation are shown in **SKILL DRILL 11-11**.

Tracheostomy Tubes

A **tracheostomy tube** is a plastic tube placed within the tracheostomy site (stoma) (**FIGURE 11-52**). It requires a 15/22-mm adapter to be compatible with ventilatory devices, such as a mechanical ventilator or bag-mask device. Patients with a tracheostomy tube may receive supplemental oxygen via tubing

designed to fit over the tube or by placing an oxygen mask over the tube. Ventilation is accomplished by simply attaching the bag-mask device to the 15-mm adapter on the tracheostomy tube.

Patients with a tracheostomy tube who experience sudden dyspnea often have thick secretions in the tube. In this case, perform suctioning through the tracheostomy tube as you would through a stoma.

When a tracheostomy tube becomes dislodged, stenosis (narrowing) of the stoma may occur. Stenosis is potentially life threatening because soft-tissue swelling decreases the diameter of the stoma and impairs the patient's ventilatory ability. Call early for paramedic backup if needed. Because a patient with a stoma already has a substantial medical injury or illness (such as brain injury or chronic respiratory insufficiency), the person may be less tolerant of even brief periods of hypoxia.

Dental Appliances

Many dental appliances can cause an airway obstruction. If a dental appliance, such as a crown or bridge, dentures, or even a piece or section of braces, has become loose, you should manually remove it before providing ventilation. Simple manual removal may relieve the obstruction and allow the patient to breathe on their own.

Providing bag-mask device or mouth-to-mask ventilation is usually much easier when dentures can be left in place. Leaving the dentures in place provides more structure to the face and will generally assist you to provide a good face-to-mask seal. Dentures and appliances may become loose or be completely out of place following an accident or as you are providing care. Periodically reassess the patient's airway to make sure the devices are firmly in place.

Special Populations

When managing the airway of an older patient, you must be aware of the presence of dentures or other dental appliances. If dentures are tight-fitting and allow for effective airway management, they should be left in place. However, if the dentures are loose, they must be removed to avoid potential airway obstruction.

Skill Drill 11-10 Ventilating Through a Stoma Using a Resuscitation Mask

Step 1

Position the patient's head in a neutral position with the shoulders slightly elevated.

Step 2

Locate and expose the stoma site.

Step 3

Place the resuscitation mask over the stoma, and ensure an adequate seal. For best results, use a pediatric mask.

Step 4

Maintain the patient's neutral head position, and ventilate the patient by exhaling directly into the resuscitation mask. Assess the patient for adequate ventilation by observing the patient's chest rise and feeling for air leaks around the mask.

Step 5

If air leakage is evident, then seal the patient's mouth and nose and ventilate.

Skill Drill 11-11 Ventilating a Stoma With a Bag-Mask Device

Step 1

With the patient's head in a neutral position, locate and expose the stoma.

Step 2

Place the bag-mask device (with a pediatric mask) over the stoma and ensure an adequate seal. Ventilate the patient by squeezing the bag-mask device and assess for adequate ventilation by observing chest rise and feeling for air leaks when using a mask. Seal the mouth and nose if an air leak is evident from the upper airway.

Step 3

Auscultate over the lungs to confirm adequate ventilation.

Facial Bleeding

Airway problems can be especially challenging in patients with serious facial injuries (**FIGURE 11-53**).

Because the blood supply in the face is so rich, injuries to the face can result in severe tissue swelling and bleeding into the airway. Control bleeding with direct pressure and suction as necessary.

Facial injuries are also associated with a high suspicion for cervical spine injury. When inserting any type of airway device, it is imperative to maintain in-line stabilization of the cervical spine.

Foreign Body Airway Obstruction

A foreign body that *completely* blocks the airway in a patient is a true emergency that will result in death if not treated immediately. In an adult, sudden foreign body airway obstruction usually occurs during a meal. In a child, it occurs while eating, playing with small toys, or crawling around the house. An otherwise healthy child who has sudden difficulty breathing has probably aspirated a foreign object.

By far, the most common airway obstruction in an unresponsive patient is the tongue, which relaxes and falls back into the throat, occluding the posterior pharynx. There are other causes of airway obstruction that do not involve foreign bodies in the airway. These include laryngeal edema (from infection or acute allergic reactions), laryngeal spasm, and trauma (tissue damage from injury). With airway obstruction from medical conditions such as infection and acute allergic reactions, repeated attempts to clear the airway as if there were a foreign body will be unsuccessful and potentially dangerous. These patients require specific emergency medical care and rapid transport to the hospital.

Words of Wisdom

Possible causes of airway obstruction:

- Relaxation of the tongue in an unresponsive patient
- Foreign objects—food, small toys, dentures
- Blood clots, bone fragments, broken teeth, or damaged oral tissue following trauma
- Airway tissue swelling—infection, allergic reaction
- Aspirated vomitus (stomach contents)
